

US010475956B2

(12) **United States Patent**  
**Atanackovic**

(10) **Patent No.:** **US 10,475,956 B2**

(45) **Date of Patent:** **Nov. 12, 2019**

(54) **OPTOELECTRONIC DEVICE**

(71) Applicant: **Silanna UV Technologies Pte Ltd,**  
Singapore (SG)

(72) Inventor: **Petar Atanackovic,** Henley Beach  
South (AU)

(73) Assignee: **Silanna UV Technologies Pte Ltd,**  
Singapore (SG)

(\* ) Notice: Subject to any disclaimer, the term of this  
patent is extended or adjusted under 35  
U.S.C. 154(b) by 0 days.

(21) Appl. No.: **14/976,814**

(22) Filed: **Dec. 21, 2015**

(65) **Prior Publication Data**

US 2016/0149075 A1 May 26, 2016

**Related U.S. Application Data**

(63) Continuation of application No. PCT/IB2015/  
052480, filed on Apr. 6, 2015.

(30) **Foreign Application Priority Data**

May 27, 2014 (AU) ..... 2014902007

(57) **ABSTRACT**

An optoelectronic device comprising a semiconductor structure includes a p-type active region and an n-type active region. The semiconductor structure is comprised solely of one or more superlattices, where each superlattice is comprised of a plurality of unit cells. Each unit cell comprises at least two distinct substantially single crystal layers.

## OPTOELECTRONIC DEVICE

## CROSS-REFERENCE TO RELATED APPLICATION

This application is a continuation of International Patent Application number PCT/IB2014/052480, filed Apr. 6, 2015, which claims priority to Australian Provisional Patent Application number 2014902007, filed May 27, 2014 and entitled "An Optoelectronic Device", both of which are incorporated herein by reference in their entirety.

## FIELD OF THE INVENTION

This invention relates generally to optoelectronic devices. In particular, the invention relates to optoelectronic devices that emit light at ultra-violet wavelengths. However, the invention is not limited to ultraviolet wavelengths.

## BACKGROUND OF THE INVENTION

Although it has been possible to produce optoelectronic devices, such as light emitting diodes (LEDs), that emit light in the deep ultra-violet (UV) wavelengths ( $\lambda \leq 280$  nm) using group III metal nitride semiconductor materials, such as aluminium gallium nitride (AlGa<sub>x</sub>N), the optical emission intensity from such LEDs to date has been relatively poor compared to visible wavelength LEDs. This is partly due to an inherent limitation in the AlGa<sub>x</sub>N semiconductor material electronic band structure. It is found that the emission of deep ultraviolet light from crystalline AlGa<sub>x</sub>N films in a direction substantially parallel to the layer formation growth axis is not favourable in traditional LED structures. In particular, deep ultraviolet LEDs are traditionally formed using a high aluminium content AlGa<sub>x</sub>N alloy in order to obtain the required bandgap for the desired optical emission wavelength. Such high aluminium content compositions are particularly affected by the aforementioned limitation.

It has been widely believed that a poor deep ultraviolet emission intensity in such LEDs is due to an inferior crystalline structural quality of deposited group III metal nitride materials which leads to poor electrical behaviour of the LEDs. In comparison with other technologically mature group III-V compound semiconductors, such as gallium aluminium arsenide (GaAlAs), the group III metal nitrides exhibit crystalline defects at least two to three orders of magnitude higher. The structural quality of the group III metal nitrides can be improved by epitaxial deposition on native substrates, such as, aluminium nitride (AlN) and gallium nitride (GaN). However, even if AlN substrates are available, the deep ultraviolet LED formed using high aluminium content AlGa<sub>x</sub>N materials is still unable to emit light efficiently in a vertical direction (i.e., parallel light emission perpendicular to the plane of the layer).

Yet a further problem exists in the prior art for operation of LEDs based on group III metal nitrides. The highest crystalline structure quality of group III metal nitride materials is formed using wurtzite crystal structure type films. These films are deposited on native or dissimilar hexagonal crystal symmetry substrates, with the so called c-plane orientation. Such c-plane oriented group III metal nitride films have the unique property of forming extremely large internal charge sheets at the interface boundary of two dissimilar AlGa<sub>x</sub>N compositions. These charges are called pyroelectric charges and appear at every layer composition discontinuity. Furthermore, each and every different AlGa<sub>x</sub>N composition possesses a slightly different crystal lattice

parameter, and therefore each dissimilar AlGa<sub>x</sub>N layer readily forms crystal misfit dislocations at the interface boundary which propagate into the interior of the layer if not correctly managed. If the dissimilar AlGa<sub>x</sub>N layers are formed to minimize the crystal misfit dislocations, then yet another problematic internal charge is generated, called a piezoelectric charge. These internal pyroelectric and piezoelectric charges therefore impose further challenges to LED design as they generate internal electric fields within the LED that tend to oppose the recombination of the charge carriers that is required for light generation.

A further problem is the inherently high refractive index of group III metal nitride materials which further limits the amount of the light generated within the LED which can escape from the surface. Significant efforts have been made in surface texturing to improve an escape cone of light from the surface. These solutions have had some success by improving the light emission from deep UV LEDs but are still far from achieving optical power densities of commercial significance when compared to UV gas-lamps technologies. Even with surface texturing, and the use of optical coupling structures, such as photonic bandgap patterned structures, UV LEDs have been unable to emit light efficiently in a vertical direction.

A yet further limitation found in the prior art is that in comparison to group III metal arsenide semiconductors, group III metal nitride semiconductors are extremely challenging to grow via film deposition. Even though a convincing range of arbitrary alloy compositions of indium gallium nitride (In<sub>x</sub>Ga<sub>1-x</sub>N), aluminium gallium nitride (Al<sub>x</sub>Ga<sub>1-x</sub>N) and indium gallium aluminium nitride (In<sub>x</sub>Ga<sub>y</sub>Al<sub>1-x-y</sub>N) have been demonstrated using both molecular beam epitaxy (MBE) and metal organic chemical vapor deposition (MOCVD), there remain large technical challenges in deposition a large number of dissimilar compositions as part of a single epitaxial stack of an LED. In practice, this limits the complexity and the range of bandgap engineered structures that can be realized using group III metal nitride semiconductors and such growth techniques.

There is therefore a need for an improved solid state optoelectronic device for use at UV frequencies, particularly deep UV frequencies. There is yet a further need to improve the film formation method for engineering such optoelectronic devices.

## SUMMARY OF THE INVENTION

In one form, although it need not be the only or indeed the broadest form, the invention resides in an optoelectronic device comprising a semiconductor structure including:

- a p-type active region; and
- an n-type active region;

wherein:

- the semiconductor structure is comprised solely of one or more superlattices;
- each superlattice is comprised of a plurality of unit cells; and
- each unit cell comprises at least two distinct substantially single crystal layers.

Preferably, the semiconductor structure is a substantially single crystal structure.

Suitably, the semiconductor structure includes an i-type active region between the n-type active region and the p-type active region.

Preferably, throughout the semiconductor structure, unit cells that are adjacent one another have substantially the same average alloy content.

Preferably, the i-type active region has a thickness of greater than or equal to 1 nm and less than or equal to 100 nm.

Preferably, the i-type active region has a lateral width selected from the range of 1 nm to approximately 10  $\mu\text{m}$ .

Preferably, the semiconductor structure is constructed by epitaxial layer growth along a predetermined growth direction.

Suitably, an average alloy content of each of the plurality of unit cells is constant within each superlattice.

Suitably, the average alloy content of each of the plurality of unit cells is constant in a substantial portion of the semiconductor structure.

Suitably, the average alloy content of each of the plurality of unit cells is non-constant along the growth direction within at least one of the one or more superlattices.

Suitably, the average alloy content of each of the plurality of unit cells varies periodically along the growth direction within a portion of at least one of the one or more superlattices.

Suitably, the average alloy content of each of the plurality of unit cells varies periodically and aperiodically along the epitaxial growth direction in distinct regions of at least one of the one or more superlattices.

Suitably, the at least two layers in each of the plurality of unit cells each have a thickness of less than or equal to 6 monolayers of a material of which the respective layer is composed along the growth direction.

Suitably, one of the at least two layers of each of the plurality of unit cells within at least a portion of the one or more superlattices comprises 1 to 10 monolayers of atoms along the growth direction and the other one or more layers in each of the respective unit cells comprise a total of 1 to 10 monolayers of atoms along the growth direction.

Suitably, all or a majority of the distinct substantially single crystal layers of each unit cell within each superlattice have a thickness of 1 monolayer to 10 monolayers of atoms along a growth direction.

Suitably, an average thickness in the growth direction of each of the plurality of unit cells is constant within at least one of the one or more superlattices.

Suitably, the unit cells in two or more of the n-type active region, the p-type active region and the i-type active region have a different average thickness.

Preferably, the at least two distinct substantially single crystal layers of each unit cell have a wurtzite crystal symmetry and have a crystal polarity in the growth direction that is either a metal-polar polarity or nitrogen-polar polarity.

Suitably, the crystal polarity is spatially varied along the growth direction, the crystal polarity being alternately flipped between the nitrogen-polar polarity and the metal-polar polarity.

Suitably, each layer in each unit cell in one or more superlattices has a thickness that is selected to control electronic and optical properties of the optoelectronic device by controlling quantized energy states and spatial wavefunctions for electrons and holes in the electronic band structure of the superlattice.

Suitably, the optoelectronic device is configured as a light emitting device and optical energy is generated by recombination of electrically active holes and electrons supplied by the p-type active region and the n-type active region, the recombination occurring in a region substantially between the p-type active region and the n-type active region.

Suitably, light emitted by the optoelectronic device is ultra violet light.

Suitably, light emitted by the optoelectronic device is ultra violet light in the wavelength range of 150 nm to 280 nm.

Suitably, light emitted by the optoelectronic device is ultra violet light in the wavelength range of 210 nm to 240 nm.

Suitably, the optoelectronic device emits light having a substantially transverse magnetic optical polarization with respect to the growth direction.

Suitably, the optoelectronic device operates as an optical waveguide with light spatially generated and confined along a direction substantially parallel to the plane of the one or more layers of the unit cells of the one or more superlattices of the semiconductor structure.

Suitably, the optoelectronic device emits light having a substantially transverse electric optical polarization with respect to the growth direction.

Suitably, the optoelectronic device operates as a vertically emitting cavity device with light spatially generated and confined along a direction substantially perpendicular to the plane of the one or more layers of the unit cells of the one or more superlattices of the semiconductor structure.

Suitably, the vertically emitting cavity device has a vertical cavity disposed substantially along the growth direction and formed using metallic reflectors spatially disposed along one or more portions of the semiconductor structure.

Suitably, the reflectors are made from a high optical reflectance metal.

Suitably, the cavity is defined by the optical length between the reflectors being less than or equal to a wavelength of the light emitted by the device.

Suitably, the wavelength is determined by the optical emission energy of the one or more superlattices comprising the semiconductor structure and optical cavity modes determined by the vertical cavity

Suitably, the high optical reflectance metal is aluminium (Al).

Suitably, at least one region of the semiconductor structure is substantially transparent to the optical energy.

Suitably, the at least one region is selected from at least one of the p-type active region and the n-type active region.

Suitably, a reflector layer is provided to improve the out coupling of the optical energy generated within the semiconductor structure.

Suitably, the reflector layer is positioned atop the optoelectronic device to substantially retroreflect emitted light from the interior of the device.

Suitably, the optoelectronic device comprises a crystalline substrate on which the semiconductor structure is grown.

Suitably, optical energy generated by the semiconductor structure is directed out of the optoelectronic device through the substrate.

Suitably, a buffer layer is grown first on the substrate followed by the semiconductor structure with the buffer acting as a strain control mechanism providing a predetermined in-plane lattice constant.

Suitably, the buffer layer includes one or more superlattices.

Suitably, a transparent region is provided adjacent to the buffer layer and the substrate, and the buffer layer is transparent to optical energy emitted from the device.

Suitably, the optical energy is coupled externally through the transparent region, the buffer layer and the substrate.

Suitably, either the p-type active region or the n-type active region is grown first.

Suitably, each of the at least two distinct substantially single crystal layers of each unit cell in each superlattice comprises at least one of the following compositions:

## 5

a binary composition single crystal semiconductor material ( $A_xN_y$ ), where  $0 < x \leq 1$  and  $0 < y \leq 1$ ;

a ternary composition single crystal semiconductor material ( $A_uB_{1-u}N_y$ ), where  $0 \leq u \leq 1$  and  $0 < y \leq 1$ ; a quaternary composition single crystal semiconductor material ( $A_pB_qC_{1-p-q}N_y$ ), where  $0 \leq p \leq 1$ ,  $0 \leq q \leq 1$  and  $0 < y \leq 1$ ;

where A, B and C are distinct metal atoms selected from group II and/or group III elements and N are cations selected from at least one of a nitrogen, oxygen, arsenic, phosphorus, antimony, and fluorine.

Suitably, each of the at least two distinct substantially single crystal layers of each unit cell in each superlattice comprises at least one of the following compositions:

- a group III metal nitride material ( $M_xN_y$ );
  - a group III metal arsenide material ( $M_xAs_y$ );
  - a group III metal phosphide material ( $M_xP_y$ );
  - a group III metal antimonide material ( $M_xSb_y$ );
  - a group II metal oxide material ( $M_xO_y$ );
  - a group II metal fluoride material ( $M_xF_y$ );
- where  $0 < x \leq 3$  and  $0 < y \leq 4$ , and where M is a metal.

Suitably, each of the at least two distinct substantially single crystal layers of each unit cell in each superlattice comprises at least one of the following compositions:

- aluminium nitride (AlN);
- aluminium gallium nitride ( $Al_xGa_{1-x}N$ ) where  $0 \leq x < 1$ ;
- aluminium indium nitride ( $Al_xIn_{1-x}N$ ) where  $0 \leq x < 1$ ;
- aluminium gallium indium nitride ( $Al_xGa_yIn_{1-x-y}N$ ) where  $0 \leq x < 1$ ,  $0 \leq y \leq 1$  and  $0 < (x+y) < 1$ .

Suitably, one or more layers of each unit cell of the one or more superlattices is not intentionally doped with an impurity species.

Suitably, one or more layers of each unit cell of the one or more superlattices of the n-type active region and/or the p-type active region is intentionally doped with one or more impurity species or formed with one or more impurity species.

Suitably, the one or more impurity species in the n-type active region are selected from:

- silicon (Si);
- germanium (Ge);
- silicon-germanium ( $Si_xGe_{1-x}$ ), where  $0 < x < 1$ ;
- crystalline silicon-nitride ( $Si_xN_y$ ), where  $0 < x < 3$  and  $0 < y < 4$ ;
- crystalline germanium-nitride ( $Ge_xN_y$ ), where  $0 < x < 3$  and  $0 < y < 4$ ;
- crystalline silicon-aluminium-gallium-nitride ( $Si_u[Al_xGa_{1-y}]_zN_v$ ) where  $u > 0$ ,  $x > 0$ ,  $0 < y < 1$ ,  $z > 0$  and  $v > 0$ ; or
- crystalline germanium-aluminium-gallium-nitride ( $Ge_u[Al_xGa_{1-y}]_zN_v$ ) where  $u > 0$ ,  $x > 0$ ,  $0 < y < 1$ ,  $z > 0$  and  $v > 0$ .

Suitably, the one or more impurity species in the p-type active region are selected from:

- magnesium (Mg);
- zinc (Zn);
- magnesium-zinc ( $Mg_xZn_{1-x}$ ), where  $0 \leq x \leq 1$ ;
- crystalline magnesium-nitride ( $Mg_xN_y$ ), where  $0 < x \leq 3$  and  $0 < y \leq 2$ ; or
- magnesium-aluminium-gallium-nitride ( $Mg_u[Al_xGa_{1-y}]_zN_v$ ), where  $u > 0$ ,  $x > 0$ ,  $0 < y < 1$ ,  $z > 0$  and  $v > 0$ .

Suitably, the one or more impurity species in the n-type active region or the p-type active region are selected from:

- hydrogen (H);
- oxygen (O);
- carbon (C); or
- fluorine (F).

Suitably, the one or more impurity species are incorporated post growth via ion-implantation.

## 6

Suitably, at least a portion of the at least one of the one or more superlattices includes uniaxial strain or a biaxial strain to enhance the activation energy of an intentionally doped region to improve an electron or hole carrier concentration.

Suitably, exposed or physically etched layers of the one or more superlattices are covered by a passivation layer.

Suitably, a first lateral contact extends partially into the n-type active region from a first contact layer formed on a surface of the n-type active region.

Suitably, a second lateral contact extends partially into the p-type active region from a second contact layer formed on a surface of the p-type active region.

Suitably, the second lateral contact is surrounded by a layer of p-type GaN between the second lateral contact and the p-type active region.

Suitably, the second contact layer is a metal contact layer and a p-type contact layer is formed between the p-type active region and the metal contact layer.

Suitably, the at least two distinct substantially single crystal layers of each unit cell each have a thickness that is less than or equal to a critical layer thickness required to maintain elastic strain.

Preferably, one or more of the at least two distinct substantially single crystal layers are distinct substantially single crystal semiconductor layers.

Suitably, one or more of the at least two distinct substantially single crystal layers are metal layers.

Further features and advantages of the present invention will become apparent from the following detailed description.

## BRIEF DESCRIPTION OF THE DRAWINGS

The accompanying figures, where like reference numerals refer to identical or functionally similar elements throughout the separate views, together with the detailed description below, are incorporated in and form part of the specification, and serve to further illustrate embodiments of concepts that include the claimed invention, and explain various principles and advantages of those embodiments.

FIG. 1 is a diagram showing a sectional view of a stack for an optoelectronic device according to a first embodiment of the present invention.

FIG. 2 is a diagram showing a sectional view of a stack for an optoelectronic device according to a second embodiment of the present invention.

FIG. 3 is a diagram showing a sectional view of an optoelectronic device according to a third embodiment of the present invention.

FIG. 4 is a diagram showing a sectional view of an optoelectronic device according to a fourth embodiment of the present invention.

FIG. 5 is a diagram showing a sectional view of an optoelectronic device according to a fifth embodiment of the present invention.

FIG. 6 is a diagram showing a sectional view of an optoelectronic device according to a sixth embodiment of the present invention.

FIG. 7 is a diagram showing a perspective view of an optoelectronic device according to a seventh embodiment of the present invention.

FIG. 8 is a diagram showing a sectional view of certain optical and electronic activity within an optoelectronic device according to an eighth embodiment of the present invention.

FIG. 9 is a graph of spatial energy levels in the conduction band and the valence band with respect to a distance along

the growth direction  $z$  for an optoelectronic device, according to an embodiment of the present invention, wherein unit cells in the p-type, i-type and n-type active regions comprise 1 monolayer of GaN and 2 monolayers of AlN.

FIG. 10 is a graph showing the quantized lowest energy electron spatial wavefunctions with respect to a distance  $z$  along the growth direction for the optoelectronic device described with reference to FIG. 9.

FIG. 11 is a graph showing the quantized lowest energy heavy hole spatial wavefunctions with respect to a distance along the growth direction for the optoelectronic device described with reference to FIG. 9.

FIG. 12 is a graph showing the spatial overlap integral of each quantized electron spatial wavefunction of FIG. 10 and the quantized heavy hole spatial wavefunction of FIG. 11 with respect to a distance along the growth direction.

FIG. 13 is a graph showing the spatial overlap integral of each quantized electron spatial wavefunction of FIG. 10 and the quantized heavy hole spatial wavefunction of FIG. 11 with respect to a combined transition energy of the corresponding electrons and holes.

FIG. 14 is a graph showing an emitted luminance versus wavelength for the optoelectronic device described with reference to FIG. 9.

FIG. 15 is a graph of spatial energy levels in the conduction band and the valence band with respect to a distance along the growth direction  $z$  for an optoelectronic device, according to an embodiment of the present invention, wherein unit cells in the p-type and n-type active regions comprise 1 monolayer of GaN and 2 monolayers of AlN, and the unit cells in the i-type active region comprise 2 monolayers of GaN and 4 monolayers of AlN.

FIG. 16 is a graph showing the quantized lowest energy electron spatial wavefunctions with respect to a distance  $z$  along the growth direction for the optoelectronic device described with reference to FIG. 15.

FIG. 17 is a graph showing the quantized lowest energy heavy hole spatial wavefunctions with respect to a distance along the growth direction for the optoelectronic device described with reference to FIG. 15.

FIG. 18 is a graph showing the spatial overlap integral of each quantized electron spatial wavefunction of FIG. 16 and the quantized heavy hole spatial wavefunction of FIG. 17 with respect to a distance along the growth direction.

FIG. 19 is a graph showing the spatial overlap integral of each quantized electron spatial wavefunction of FIG. 16 and the quantized heavy hole spatial wavefunction of FIG. 17 with respect to a combined transition energy of the corresponding electrons and holes.

FIG. 20 is a graph showing an emitted luminance versus wavelength for the optoelectronic device described with reference to FIG. 15.

FIG. 21 is a graph of spatial energy levels in the conduction band and the valence band with respect to a distance along the growth direction  $z$  for an optoelectronic device, according to an embodiment of the present invention, wherein unit cells in the p-type and n-type active regions comprise 2 monolayer of GaN and 2 monolayers of AlN, and the unit cells in the i-type active region comprise 3 monolayers of GaN and 3 monolayers of AlN.

FIG. 22 is a graph showing the quantized lowest energy electron spatial wavefunctions with respect to a distance  $z$  along the growth direction for the optoelectronic device described with reference to FIG. 21.

FIG. 23 is a graph showing the quantized lowest energy heavy hole spatial wavefunctions with respect to a distance

along the growth direction for the optoelectronic device described with reference to FIG. 21.

FIG. 24 is a graph showing the spatial overlap integral of each quantized electron spatial wavefunction of FIG. 22 and the quantized heavy hole spatial wavefunction of FIG. 23 with respect to a distance along the growth direction.

FIG. 25 is a graph showing the spatial overlap integral of each quantized electron spatial wavefunction of FIG. 22 and the quantized heavy hole spatial wavefunction of FIG. 23 with respect to a combined transition energy of the corresponding electrons and holes.

FIG. 26 is a graph showing an emitted luminance versus wavelength for the optoelectronic device described with reference to FIG. 21.

FIG. 27A is a view of a wurtzite crystal structure for a group III metal nitride semiconductor.

FIG. 27B is a view of the c-plane of the wurtzite crystal structure of FIG. 27A.

FIG. 27C is a perspective view of an AlN wurtzite crystal oriented along the c-axis and exposing an Al atom surface.

FIG. 28 is a chart showing the preferred range of layered thicknesses for an example superlattice.

FIG. 29 is a side view of a crystal lattice structure of a unit cell of a superlattice, according to an embodiment of the present invention.

FIG. 30 is a chart showing further possible implementations of unit cells formed by using on GaN and AlN materials.

FIG. 31 is a graph of an equilibrium in-plane lattice constant  $a_{\parallel}^{SL}$  of a superlattice for a given selection of M monolayers of GaN and N monolayers of AlN in each unit cell.

FIG. 32 is a schematic showing some of the atomic forces present in a structure comprising two unit cells.

FIG. 33 is a graph of an equilibrium in-plane lattice constant  $a_{\parallel}^{SL}$  of a superlattice for a given selection of M monolayers of GaN and N monolayers of AlN in each unit cell, where  $M=N$ .

FIG. 34 is a graph of an equilibrium in-plane lattice constant  $a_{\parallel}^{SL}$  of a superlattice for a given selection of M monolayers of GaN and N monolayers of AlN in each unit cell, where  $N=2M$ .

FIG. 35 is a graph of a calculated portion of the energy band structure of a superlattice having 100 unit cells that each comprise 5 monolayers of GaN and 5 monolayers of AlN.

FIG. 36 shows a superlattice used to simulate a semi-infinite number of periods of a superlattice of constant unit cell length and composition.

FIG. 37 is a graph of a transverse electric (TE) optical emission spectra of a superlattice having repeated unit cell that comprises 1 monolayer of GaN and 2 monolayers of AlN.

FIG. 38 is a graph of a TE optical emission spectra of a superlattice having repeated unit cell that comprises 2 monolayers of GaN and 4 monolayers of AlN.

FIG. 39 is a graph of a TE optical emission spectra of a superlattice having repeated unit cell that comprises 3 monolayers of GaN and 6 monolayers of AlN.

FIG. 40 is a graph of a TE optical emission spectra of a superlattice having repeated unit cell that comprises 4 monolayers of GaN and 8 monolayers of AlN.

FIG. 41 is a graph of a TE optical emission spectra of a superlattice having repeated unit cell that comprises 5 monolayers of GaN and 10 monolayers of AlN.

FIG. 42 is a graph comparing the optical emission spectra shown in each of FIGS. 37 to 41 for a heavy hole transition.

FIG. 43 is a graph of the calculated optical emission wavelength of the lowest energy transition between the allowed superlattice conduction band states and the heavy hole states for a selection of superlattices having M monolayers of GaN and N monolayers of AlN in each unit cell, where  $N=2M$ .

FIG. 44 is a graph of the calculated optical emission wavelength of the lowest energy transition between the allowed superlattice conduction band states and the heavy hole states for a selection of superlattices having M monolayers of GaN and N monolayers of AlN in each unit cell, where  $M=N$ .

FIG. 45 is a graph of a conduction band energy and a heavy hole valence band energy for a semiconductor structure that has 25 unit cells comprising 2 monolayers of GaN and 4 monolayers of AlN in the i-type active region.

FIG. 46 is a graph of a conduction band energy and a heavy hole valence band energy for a semiconductor structure that has 100 unit cells comprising 2 monolayers of GaN and 4 monolayers of AlN in the i-type active region.

FIG. 47 is a graph showing the graphs of FIGS. 45 and 46 on a single graph for comparison.

FIG. 48 is a graph of the quantized lowest energy electron wavefunctions within the i-type active region of the semiconductor structure referred to in FIG. 45 under the influence of the built-in depletion electric field.

FIG. 49 is a graph of the quantized lowest energy heavy hole wavefunctions within the i-type active region of the semiconductor structure referred to in FIG. 46 under the influence of the built-in depletion electric field.

FIG. 50A is a graph of the emission spectra from the i-type active region of the devices referred to in FIG. 45.

FIG. 50B is a graph of the emission spectra from the i-type active region of the devices referred to in FIG. 46.

FIG. 51 is a schematic showing the influence of the built-in depletion field on the conduction band edge, the delocalized electron wavefunction and the energy miniband.

Skilled artisans will appreciate that elements in the figures are illustrated for simplicity and clarity and have not necessarily been drawn to scale. For example, the dimensions of some of the elements in the figures may be exaggerated relative to other elements to help to improve understanding of embodiments of the present invention.

The optoelectronic device components have been represented where appropriate by conventional symbols in the drawings, showing only those specific details that are pertinent to understanding the embodiments of the present invention so as not to obscure the disclosure with details that will be readily apparent to those of ordinary skill in the art having the benefit of the description herein.

#### DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

According to one aspect, the invention resides in an optoelectronic device comprising a semiconductor structure. In preferred embodiments, the semiconductor structure is constructed by growth, for example, epitaxial layer growth, along a predetermined growth direction. The semiconductor structure is comprised solely of one or more superlattices. For example, where the semiconductor structure comprises more than one superlattice, the superlattices are formed atop one another in a contiguous stack. In preferred embodiments, the one or more superlattices are short period superlattices. Each of the one or more superlattices is comprised of a plurality of unit cells, and each of the plurality of unit cells comprises at least two distinct substantially single

crystal layers. In preferred embodiments, one or more of the at least two distinct substantially single crystal layers are distinct single crystal semiconductor layers, and more preferably all of the at least two distinct substantially single crystal layers are distinct single crystal semiconductor layers. However, in some embodiments, one or more of the at least two distinct substantially single crystal layers are metal layers. For example, the metal layers can be formed of aluminium (Al).

The semiconductor structure includes a p-type active region and an n-type active region. The p-type active region of the semiconductor structure provides p-type conductivity and an n-type active region provides n-type conductivity. In preferred embodiments, the semiconductor structure includes an i-type active region between the n-type active region and the p-type active region to form a p-i-n device.

In some embodiments, each region of the semiconductor structure is a separate superlattice. However, in some alternative embodiments, the n-type active region, the p-type active region and/or the i-type active region are regions of a single superlattice. In other alternative embodiments, the active region, the p-type active region and/or the i-type active region each comprise one or more superlattices.

In preferred embodiments, the optoelectronic device is a light emitting diode or a laser and/or emits ultra violet light, preferably, in the wavelength range of 150 nm to 280 nm, and more preferably in the wavelength range of 210 nm to 240 nm. However, in alternative embodiments, the optoelectronic device emits ultra violet light, preferably, in the wavelength range of 240 nm to 300 nm, and more preferably in the wavelength range of 260 nm to 290 nm. When the optoelectronic device is configured as a light emitting device, the optical energy is generated by recombination of electrically active holes and electrons supplied by the p-type active region and the n-type active region. The recombination of holes and electrons occurs in a region substantially between the p-type active region and the n-type active region, for example, in the i-type active region or around an interface of the p-type active region and n-type active region when an i-type active region is omitted.

Each layer in each unit cell in the one or more superlattices has a thickness that can be selected to control electronic and optical properties of the optoelectronic device by controlling quantized energy states and spatial wavefunctions for electrons and holes in the electronic band structure of the superlattice. From this selection a desired electronic and optical energy can be achieved. In preferred embodiments, an average thickness in the growth direction of each of the plurality of unit cells is constant within at least one of the one or more superlattices. In some embodiments, the unit cells in two or more of the n-type active region, the p-type active region and the i-type active region have a different average thickness.

In preferred embodiments, one of the at least two layers of each of the plurality of unit cells within at least a portion of the one or more superlattices comprises 1 to 10 monolayers of atoms along the growth direction and the other one or more layers in each of the respective unit cells comprise a total of 1 to 10 monolayers of atoms along the growth direction. In some embodiments, all or a majority of the distinct substantially single crystal layers of each unit cell within each superlattice have a thickness of 1 monolayer to 10 monolayers of atoms along a growth direction. In some embodiments, at least two layers in each of the plurality of unit cells each have a thickness of less than or equal to 6 monolayers of a material of which the respective layer is

composed along the growth direction. In some embodiments, the thickness of each unit cell is chosen based on the composition of the unit cell.

An average alloy content of each of the plurality of unit cells can be constant or non-constant along the growth direction within at least one of the one or more superlattices. Maintaining a constant average alloy content enables lattice matching of the effective in-plane lattice constant of the unit cells of dissimilar superlattices. In preferred embodiments, throughout the semiconductor structure, unit cells that are adjacent one another have substantially the same average alloy content. In some embodiments, the average alloy content of each of the plurality of unit cells is constant in a substantial portion of the semiconductor structure.

In some embodiments, the average alloy content of each of the plurality of unit cells varies periodically and/or aperiodically along the growth direction within a portion of at least one of the one or more superlattices. In some embodiments, the average alloy content of each of the plurality of unit cells varies periodically and aperiodically along the epitaxial growth direction in distinct regions of at least one of the one or more superlattices.

In preferred embodiments, the at least two distinct substantially single crystal layers of each unit cell have a wurtzite crystal symmetry and have a crystal polarity in the growth direction that is either a metal-polar polarity or nitrogen-polar polarity. In some embodiments, the crystal polarity is spatially varied along the growth direction, the crystal polarity being alternately flipped between the nitrogen-polar polarity and the metal-polar polarity.

Preferably, each of the at least two distinct substantially single crystal layers of each unit cell in each superlattice comprises at least one of the following compositions: a binary composition single crystal semiconductor material ( $A_xN_y$ ), where  $0 < x \leq 1$  and  $0 < y \leq 1$ ; a ternary composition single crystal semiconductor material ( $A_uB_{1-u}N_y$ ), where  $0 \leq u \leq 1$  and  $0 < y \leq 1$ ; a quaternary composition single crystal semiconductor material ( $A_pB_qC_{1-p-q}N_y$ ), where  $0 \leq p \leq 1$ ,  $0 \leq q \leq 1$  and  $0 < y \leq 1$ . Here A, B and C are distinct metal atoms selected from group II and/or group III elements and N are cations selected from at least one of a nitrogen, oxygen, arsenic, phosphorus, antimony, and fluorine.

More preferably, each of the at least two distinct substantially single crystal layers of each unit cell in each superlattice comprises at least one of the following compositions: a group III metal nitride material ( $M_xN_y$ ); a group III metal arsenide material ( $M_xAs_y$ ); a group III metal phosphide material ( $M_xP_y$ ); a group III metal antimonide material ( $M_xSb_y$ ); a group II metal oxide material ( $M_xO_y$ ); a group II metal fluoride material ( $M_xF_y$ ). Here  $0 < x \leq 3$  and  $0 < y \leq 4$ , and where M is a metal. In some embodiments, the metal M is selected from one or more group II, group III or group IV elements. For example, each of the at least two distinct substantially single crystal layers of each unit cell in each superlattice comprises at least one of the following compositions: aluminium nitride (AlN); aluminium gallium nitride ( $Al_xGa_{1-x}N$ ) where  $0 \leq x < 1$ ; aluminium indium nitride ( $Al_xIn_{1-x}N$ ) where  $0 \leq x < 1$ ; aluminium gallium indium nitride ( $Al_xGa_yIn_{1-x-y}N$ ) where  $0 \leq x < 1$ ,  $0 \leq y \leq 1$  and  $0 < (x+y) < 1$ . In some embodiments, one of the at least two distinct substantially single crystal layers comprises a narrower band gap material and another of the at least two distinct substantially single crystal layers comprises a wider bandgap material.

In some embodiments, one or more of the at least two distinct substantially single crystal layers of each unit cell is

formed of a metal. For example, each unit cell can comprise an aluminium (Al) layer and an aluminium nitride (AlN) layer.

In some embodiments, one or more layers of each unit cell of the one or more superlattices is not intentionally doped with an impurity species, for example, in the n-type active region, the p-type active region and/or the i-type active region. Alternatively or additionally, one or more layers of each unit cell of the one or more superlattices of the n-type active region and/or the p-type active region is intentionally doped with one or more impurity species or formed with one or more impurity species. For example, the one or more impurity species in the n-type active region are selected from: silicon (Si); germanium (Ge); silicon-germanium ( $Si_xGe_{1-x}$ ), where  $0 < x < 1$ ; crystalline silicon-nitride ( $Si_xN_y$ ), where  $0 < x < 3$  and  $0 < y < 4$ ; crystalline germanium-nitride ( $Ge_xN_y$ ), where  $0 < x < 3$  and  $0 < y < 4$ ; crystalline silicon-aluminium-gallium-nitride ( $Si_u[Al_xGa_{1-y}]_zN_v$ ) where  $u > 0$ ,  $x > 0$ ,  $0 < y < 1$  and  $v > 0$ ; or crystalline germanium-aluminium-gallium-nitride ( $Ge_u[Al_xGa_{1-y}]_zN_v$ ) where  $u > 0$ ,  $x > 0$ ,  $0 < y < 1$  and  $v > 0$ . For example, the one or more impurity species in the p-type active region are selected from: magnesium (Mg); zinc (Zn); magnesium-zinc ( $Mg_xZn_{1-x}$ ), where  $0 \leq x \leq 1$ ; crystalline magnesium-nitride ( $Mg_xN_y$ ), where  $0 < x \leq 3$  and  $0 < y \leq 2$ ; or magnesium-aluminium-gallium-nitride ( $Mg_u[Al_xGa_{1-y}]_zN_v$ ), where  $u > 0$ ,  $x > 0$ ,  $0 < y < 1$  and  $v > 0$ . The one or more impurity species in the n-type active region or the p-type active region can also be selected from: hydrogen (H); oxygen (O); carbon (C); or fluorine (F).

At least a portion of the at least one of the one or more superlattices can include a uniaxial strain, a biaxial strain or a triaxial strain to modify a level of activated impurity doping. That is, by the action of crystal deformation in at least one crystal direction, the induced strain can deform advantageously the energy band structure of the materials in the layers of the one or more superlattices. The resulting energy shift of the conduction or valence band edges can then be used to reduce the activation energy of a given impurity dopant relative to the superlattice. For example, a group III nitride material such as p-type Mg-doped GaN with a wurtzite lattice structure can be subjected to an elastic tensile strain substantially parallel to the c-plane and perpendicular to the growth direction. The resulting shift in energy of the valence band edges results in a reduced energy separation between the said valence band edge and the Mg impurity level. This energy separation is known as the activation energy for holes and is temperature dependent. Therefore, reducing the activation energy of a specific carrier due to an impurity dopant via the application of a strain dramatically improves the activated carrier density of the doped material. This built-in strain can be selected during an epitaxial material formation step during the formation of the superlattice. For example, a GaN epilayer can be formed to include a tensile in-plane strain if deposited directly upon a single crystal AlN layer. If, for example, in the p-type active region, the AlN and Mg doped GaN layers are each limited in thickness to 1 to 7 monolayers, then they will both elastically deform without the creation of deleterious crystal defects, such as interfacial dislocations. Here the AlN layer will undergo an in-plane compressive stress, whereas the Mg-doped GaN layer will undergo in-plane tensile stress. Therefore, strain can enhance the activation energy of one or more of the intentionally doped regions that contain the impurity species. This improves an electron or hole carrier concentration in the one or more of the intentionally doped regions.

FIG. 1 is a diagram showing a sectional view of a stack **100** for an optoelectronic device according to some embodiments of the present invention. In one embodiment, the optoelectronic device is a Light Emitting Diode (LED). However, it should be appreciated that the present invention may also be adapted to fabricate superluminescent LEDs and lasing devices with the positioning of suitable reflective layers or mirrors in the optoelectronic device.

The stack **100** comprises a crystalline substrate **110**. A buffer region **112** is grown first on the substrate **110** followed by a semiconductor structure **114**. The buffer region **112** and the semiconductor structure **114** are formed or grown in a growth direction indicated by arrow **101**. The buffer region **112** includes a buffer layer **120** and one or more superlattices **130**. In preferred embodiments, the buffer region acts as a strain control mechanism providing a predetermined in-plane lattice constant.

The semiconductor structure **114** comprises, in growth order, an n-type active region **140**, an i-type active region **150** and a p-type active region **160**. A p-type contact layer **170** is optionally formed on the p-type active region **160**. A first contact layer **180** is formed on the p-type contact layer **170** or the p-type active region **160** if the p-type contact layer is not present. In preferred embodiments, at least one region of the semiconductor structure is substantially transparent to an optical energy emitted by the optoelectronic device. For example, the p-type active region and/or the n-type active region are transparent to the emitted optical energy.

In preferred embodiments, the substrate **110** has a thickness of between 300  $\mu\text{m}$  and 1,000  $\mu\text{m}$ . The thickness of the substrate **110** can be chosen based on a diameter of the substrate **110**. For example, a substrate having a diameter of two inches (25.4 mm) and made of c-plane sapphire may have a thickness of about 400  $\mu\text{m}$  and a substrate having a diameter of six inches may have a thickness of about 1 mm. The substrate **110** can be a native substrate made of a native material that is native to the n-type active region or a non-native substrate made from a non-native material that is non-native to the n-type active region. For example, if the n-type active region comprises one or more group III metal nitride materials, the substrate **110** can be made of a similar group III metal nitride material, such as AlN or GaN, or from a non-native material, such as  $\text{Al}_2\text{O}_3$  or Si(111). However, a person skilled in the art will realize that the substrate **110** may be made from many other materials which are compatible with a layer formed above the substrate **110**. For example, the substrate can be made of a crystalline metal oxide material, such as magnesium oxide (MgO) or zinc-oxide (ZnO), silicon-carbide (SiC), Calcium Fluoride ( $\text{CaF}_2$ ), a crystalline thin film semiconductor on amorphous glass, or a crystalline thin film semiconductor on a metal.

The buffer region **112** functions as a transition region between the substrate **110** and semiconductor structure **114**. For example, the buffer region **112** provides a better match in lattice structure between the substrate **110** and the semiconductor structure **114**. For example, the buffer region **112** may comprise a bulk like buffer layer followed by at least one superlattice designed to achieve a desired in-plane lattice constant suitable for depositing the one or more superlattices of the semiconductor structure of the device.

In preferred embodiments, the buffer layer **120** in the buffer region **112** has a thickness of between 50 nm and several micrometres, and preferably, between 100 nm and 500 nm. The buffer layer **120** can be made from any material that is suitable for matching the lattice structure of the substrate **110** to the lattice structure of a lowest layer of the

one or more superlattices. For example, if the lowest layer of the one or more superlattices is made of a group III metal nitride material, such as AlN, the buffer layer **120** can be made of AlN. In alternative embodiments, the buffer layer **120** can be omitted.

The one or more superlattices **130** in the buffer region **112** and the one or more superlattices in the semiconductor structure **114** can be considered to comprise a plurality of unit cells. For example, the unit cells **132** in the buffer region **112**, the unit cells **142** in the n-type active region **140**, the unit cells **152** in the i-type active region **150**, and the unit cells **162** of the p-type active region **160**. Each of the plurality of unit cells comprises two distinct substantially single crystal layers. A first layer in each unit cell is labelled "A" and a second layer in each unit cell is labelled "B".

In different regions of the semiconductor structure, the first layer and/or the second layer in each unit cell can have the same or a different composition, and/or the same or a different thickness. For example, FIG. 1 shows the first layers and the second layers having a greater thickness in the i-type active region **150** than in the n-type active region **140** and the p-type active region **160**.

The n-type active region **140** provides n-type conductivity. In preferred embodiments, one or both of the first layer **142A** and the second layer **142B** in each unit cell **142** in the n-type active region **140** is doped with, or formed of, a dopant material, such as the materials described above. In some embodiments, the dopant material is different in the first layer and the second layer of each unit cell.

The i-type active region **150** is the main active region of the optoelectronic device. In preferred embodiments, the i-type active region is designed to optimize the spatial electron and hole recombination to a selected emission energy or wavelength. In preferred embodiments, the first layer **152A** and the second layer **152B** in each unit cell **152** of the i-type active region **150** have a thickness that is adjusted to control the quantum mechanical allowed energies within the unit cell or the i-type active region **150**. As the thickness of each layer of the unit cells is 1 to 10 monolayers in preferred embodiments, a quantum description and treatment of the superlattice structure is necessary to determine the electronic and optical configuration. If group III metal nitride materials having a wurtzite crystal symmetry and further having a polar nature are used to form the layers, there are many internal electric fields across each heterojunction of the unit cell and the one or more superlattices. These built in electric fields form due to spontaneous and piezoelectric charges that occur at each heterojunction. The complex spatial band structure along the growth direction creates a non-trivial potential variation in the conduction and valence bands which is modulated by the spatial variation in composition between the layers of the unit cells. This spatial variation is of the order of the deBroglie wavelength of the respective carriers within the conduction and valence bands, and thus requires a quantum treatment of the resulting confined energy levels and spatial probability distribution (defined herein as the carrier wavefunction) within the one or more superlattices.

Furthermore, a crystal polarity of the semiconductor structure is preferably selected from either a metal-polar or a nitrogen-polar growth along the growth direction **101**, for example, for one or more superlattices formed of group III metal nitride materials. Depending on the crystal polarity of the semiconductor structure, at least a portion of the i-type active region **150** can be further selected to optimize the optical emission. For example, a metal-polar oriented growth along the growth direction **101**, can be used to form

15

a superlattice in the i-type active region of an n-i-p stack comprising alternating layers of GaN and AlN. As the n-type active region in an n-i-p stack is formed closest to the substrate, the i-type active region will have a linearly increasing depletion field across it spanning the distance between the n-type active region and the p-type active region (for example, see FIGS. 9, 15 and 21). The i-type active region superlattice will then be subjected to yet a further electric field due to the built-in depletion field of the n-i-p stack. Alternatively, the built-in depletion field across the i-type active region can be generated in other configurations. For example, the stack can be a p-i-n stack with the p-type active region 160 closest to the substrate and/or grown using nitrogen-polar crystal growth orientation along 101.

The said depletion field across the depletion region of a p-n stack or the i-type active region 150 of a p-i-n stack can also partially set an optical emission energy and emission wavelength of the optoelectronic device. In preferred embodiments, one or both of the first layer 152A and the second layer 152B in each unit cell in the i-type active region is un-doped or not intentionally doped. In preferred embodiments, the i-type active region 150 has a thickness of less than or equal to 100 nm and a thickness of greater than or equal to 1 nm. The i-type active region has a lateral width selected from the range of 1 nm to approximately 10  $\mu\text{m}$ .

The total width of the i-type active region 150 can be selected to further tune the depletion field strength across the i-type active region 150 between the p-type active region 160 and the n-type active region 140. Depending upon the crystal growth polarity, the width and the effective electron and hole carrier concentrations of the n-type active region 140 and the p-type active region 160, the depletion field strength will provide either a blue-shift or a red-shift in the emission energy or wavelength of the light emitted from the i-type active region.

The p-type active region 160 provides p-type conductivity. In preferred embodiments, one or both of the first layer 162A and the second layer 162B in each unit cell 162 in the p-type active region is doped with, or formed of, a dopant material, such as the materials described above.

In preferred embodiments, the first layer and the second layer of each of the plurality of unit cells in each of the one or more superlattices in the semiconductor structure are composed of group III metal nitride materials. For example, the first layers can be composed of aluminium nitride (AlN), and the second layers can be composed of gallium nitride (GaN). However, it should be appreciated that the first and second layers in each of the one or more superlattices can be composed of any of the materials specified above.

In preferred embodiments, the average alloy content, for example Al and/or Ga where the first layers consist essentially of AlN and the second layers consist essentially of GaN, of the one or more superlattices is constant. In alternative embodiments, the average alloy content of one or more of the one or more superlattices is non-constant.

In some embodiments, the average alloy content of the unit cells is the same in all superlattices of the semiconductor structure 114 and/or stack 100, but the period is changed between superlattices and/or within superlattices. Maintaining a constant average alloy content enables lattice matching of dissimilar superlattices. Such lattice matched growth of each unit cell enables large numbers of periods to be formed without an accumulation of strain. For example, using a specific period of the superlattice for an n-type active region 140 would make the n-type active region 140 more transparent to a wavelength of the emitted light. In another

16

example, using a different period for the i-type active region 150, would cause the light to be emitted vertically i.e. in a same plane as the growth direction 101.

In another embodiment, the one or more superlattices have constant average alloy content and an optical emission that is substantially perpendicular to the plane of the superlattice layers. For example, a vertically emitting device is formed by using superlattices with layers of AlN and AlGaIn with the Al percentage of the AlGaIn layers less than 60%. In yet another preferred embodiment, a plurality of or all of the one or more the superlattices are constructed from unit cells comprising AlN and GaN thereby enabling an improved growth process that is optimized at a single growth temperature for only two materials.

Doping may be incorporated into the n-type active region and/or p-type active region of the one or more superlattices in several ways. In some embodiments, doping is introduced into just one of the first layer and the second layer in each unit cell. For example, Si can be introduced into GaN in the second layer of the unit cell to create an n-type material or Mg can be introduced into GaN in the second layer of the unit cell to create a p-type material. In alternative embodiments, doping can be introduced into more than one layer/material in each unit cell and the dopant material can be different in each layer of the unit cell. In some embodiments, the one or more superlattices include a uniaxial strain or a biaxial strain to modify a level of activated doping.

In preferred embodiments, the one or more superlattices of the semiconductor structure comprise a wurtzite lattice structure, preferably grown along the c-axis (0001). Where the one or more superlattices have a wurtzite lattice structure, a monolayer is defined as half a thickness of the "c" dimension of the hexagonal unit cell of the lattice. In some embodiments, the one or more superlattices of the semiconductor structure comprise a zinc-blend lattice structure, preferably grown along (001)-axis. Where the one or more superlattices have a zinc-blend lattice structure, one monolayer is defined as half a thickness of the "a" dimension of the cubic unit cell of the lattice.

While a single superlattice is shown in FIG. 1 for each region of the semiconductor structure, it should be appreciated that each region may include more than one superlattice stacked atop one another. For example, the n-type active layer 140 can include a first superlattice wherein respective layers in each unit cell have a first material composition and a second superlattice grown on the first super lattice wherein the respective layers in each unit cell have a second material composition. In some embodiments, the stack 100 can comprise a single superlattice comprising one or more of the buffer region 130, the n-type active region 140, the i-type active region 150 and the p-type active region 160.

In some embodiments, at least one of the one or more superlattices is periodic, meaning that each unit cell of the respective superlattice has the same structure. For example, each unit cell of the respective superlattice has the same number of layers, the same layer thicknesses and the same material compositions in respective layers.

In some embodiments, at least one of the one or more superlattices is aperiodic meaning that one of more of the unit cells have a different structure. The differences can be in materials chosen for each of the layers, the thicknesses of the layers, the number of layers in each unit cell, or a combination thereof.

Each of the superlattices may have a different structure to achieve different electronic and optical properties. Thus, one superlattice could be periodic, while the others could be aperiodic. In addition, all of the superlattices in a stack 100

can be periodic, or all of the superlattices can be aperiodic. In yet another embodiment, one or more superlattices can be periodic, while one or more superlattices are aperiodic. For example, a superlattice in the buffer region **130** can be aperiodic to assist in lattice matching.

The p-type contact layer **170** also known as a hole injection layer is formed on top of the p-type active region of the one or more superlattices. A first contact layer **180** is formed on the p-type contact layer **170**, such that the p-type contact layer **170** is formed between the first contact layer **180** and the p-type active region **160**. In preferred embodiments, the first contact layer **180** is a metal contact layer. The p-type contact layer **170** aids an electrical ohmic contact between the p-type active region **160** and the first contact layer **180**. In preferred embodiments, the p-type contact layer **170** is made from p-type GaN and has a thickness of between 5 nm and 200 nm, and preferably, between 10 nm and 25 nm. The thickness of the p-type contact layer **170** can be optimized to reduce the optical absorption at a specific optical wavelength and/or to make the p-type contact layer **170** optically reflective to an emission wavelength of the stack **100**.

The first contact layer **180** enables the stack **100** to be connected to a positive terminal of a voltage source. In preferred embodiments, the first contact layer **180** has a thickness of between 10 nm and several 1000 nm, and preferably, between 50 nm and 500 nm.

A second contact layer (not shown) is formed on the n-type active region **140** to connect to a negative terminal of a voltage source. In preferred embodiments, the second contact layer has a thickness of between 10 nm and several 1000 nm, and preferably, between 50 nm and 500 nm.

The first contact layer **180** and the second contact layer may be made from any suitable metal. In preferred embodiments, the first contact layer **180** is made from a high work function metal to aid in the formation of a low ohmic contact between the p-type active region **160** and the first contact layer **180**. If the work function of the first contact layer **180** is sufficiently high, then the optional p-type contact layer **170** may not be required. For example, if the substrate is transparent and insulating, the light emitted by the semiconductor structure is directed substantially out through the substrate and the p-type active region **160** is disposed further from the substrate than the n-type active region **140**, then the first contact layer **180** should ideally have the property of high optical reflectance at the operating wavelength, so as to retroreflect a portion of the emitted light back through the substrate. For example, the first contact layer **180** can be made from metals selected from Aluminium (Al), Nickel (Ni), Osmium (Os), Platinum (Pt), Palladium (Pd), Iridium (Ir), and Tungsten (W). Especially, for deep ultraviolet (DUV) operation in which the stack **100** emits DUV light, the first contact layer **180** may not in general fulfil the dual specification of low p-type ohmic contact and high optical reflectance. High work function p-type contact metals for group III metal nitrides are generally poor DUV wavelength reflectors. Platinum (Pt), Iridium (Ir), Palladium (Pd) and Osmium (Os) are an ideal high work function p-type contact metals to high Al % group III metal nitride compositions and superlattices. In preference, Osmium is a superior low ohmic contact metal to p-type regions comprising group III metal nitrides.

However, for ultraviolet and DUV operation of the stack **100**, aluminium is the most preferred of all metals, as it has the highest optical reflectance over a large wavelength range spanning from 150 to 500 nm. In general, metals are preferred as DUV optical reflectors due to the low penetra-

tion depth and low loss of light into the metal. This enables optical microcavity structures to be formed. Conversely, relatively low work function metals, such as Aluminium (Al), Titanium (Ti) and Titanium Nitride (TiN) can be utilized to form low ohmic metal contacts to n-type group III metal nitride compositions and superlattices.

It should be appreciated that the stack **100** shown in FIG. **1** is an exemplary stack for an optoelectronic device, and that the stack **100** may be made in many other ways. For example, the n-type active layer **140** and the p-type active layer **160** may be reversed such that the p-type layer **160** is grown first. However, a reason for growing the n-type active layer **140** first is that it is generally less challenging to grow a low defect density n-type superlattice using group III metal nitride compositions on a substrate or buffer layer than a p-type superlattice. It should also be noted that the buffer layer **120** and/or the buffer region **130** are optional layers, and the one or more superlattices can be grown directly on the substrate **110**. However it is generally easier to grow the one or more superlattices on the buffer layer **120** and/or buffer region **130**, as the surfaces of such layers/regions are generally oriented in the c-plane of the crystal.

In some embodiments, the buffer region and the adjacent p-type or n-type active region are part of the same superlattice with the only difference between the buffer region and the p-type or n-type active region being the incorporation of an impurity dopant in the p-type or n-type active region. In some embodiments, a first superlattice is grown upon the substrate with a sufficient thickness to render the superlattice in a substantially relaxed or free standing state with a low defect density and a preselected in-plane lattice constant.

In another embodiment, the stack **100** may be fabricated without an i-type active layer **150** such that the stack forms a p-n junction rather than the p-i-n junction of FIG. **1**. Furthermore, it should be appreciated that p-type contact layer **170** is optional, and the first contact layer **180** may be grown directly on the p-type active region **160** of the one or more superlattices. However, it is more difficult to fabricate the first contact layer **180** directly on the p-type active region **160** using conventional ex-situ fabrication techniques. For example a thin but heavily doped p-type contact layer **170** enables easier and more consistent post epitaxial process for metallization to achieve an ohmic contact. However, an in-situ metallization process directly onto a final epitaxial surface of the p-type active region **160** that is free of contamination provides an alternate means for formation of the first contact layer **180**.

In preferred embodiments, the one or more superlattices are grown sequentially during at least one deposition cycle. That is dopants are introduced during epitaxy via a process of co-deposition. An alternative method is to physically grow at least a portion of the one or more superlattices without a dopant and then, post-growth, introduce the desired dopant. For example, experiments have found that n-type group III metal nitride materials are typically superior in crystal structure quality to p-type group III metal nitride materials. Therefore, in some embodiments, p-type materials are deposited as the final sequence of the fabrication of the stack. A post growth method for incorporating dopant introduced from a surface can then be used. For example, ion-implantation, and diffusion (e.g., via a spin-on dopant) followed by activation thermal anneals.

The semiconductor structure **114** can be grown with a polar, non-polar or semi-polar crystal polarity oriented along the growth direction **101**. For example, a wurtzite lattice structure can be grown which is oriented with the hexagonal symmetry of the c-plane being substantially perpendicular to

the growth direction. The plane of so formed unit cell layers are then said to be oriented upon a c-plane. Ionic wurtzite crystals such as the group III metal nitrides, further form polar crystals (that is, crystals that lack a centre of inversion symmetry). These polar crystals can be metal-polar or nitrogen polar along a crystal direction perpendicular to the c-plane.

Other growth plane orientations can also be achieved resulting in semi-polar and even non-polar crystal growth along the growth direction **101**. A semiconductor structure formed of group III metal nitrides in a non-polar orientation can be via growth of a cubic and/or zinc-blend lattice structure. However, when the semiconductor structure is formed with such lattice structures it is typically less stable than when the semiconductor structure is formed with a wurtzite lattice structure. For example, group III metal nitrides can be grown with a semi-polar crystal polarity on an r-plane sapphire substrate, resulting in one or more a-plane oriented superlattices.

Reducing the crystal polarity from a polar to a semi-polar crystal along a growth direction is advantageous for the reduction of the spontaneous and piezoelectric charges that are created at each and every heterojunction. While such semi-polar and non-polar crystal polarities have some advantages, it is found that the highest crystalline quality superlattices are formed using wurtzite crystal structures having a single crystal polarity oriented along a growth direction. The internal polarization charges can be managed advantageously by keeping the effective alloy content constant in each unit cell of the one or more superlattices. Once the average alloy content in any one unit cell or superlattice varies from another, a net polarization charge is accumulated. This can be used advantageously to control the band edge energy position in the one or more superlattices relative to the Fermi energy.

For example, a wurtzite lattice can have charge polarization at the interface between layers of the unit cells when the first layers and second layers are composed of GaN and AlN respectively. By using one or more superlattices for the n-type active region, the i-type active region and the p-type active region, varying the period to tune the optoelectronic device and keeping an average Al content in each unit cell constant, the charge polarisation at the interfaces in the optoelectronic stack **100** can be reduced.

In a further embodiment, a single superlattice structure is used for n-type active region **140**, the i-type active region **150**, and the p-type active region **160** and the superlattice is strained via biaxial and or uniaxial stresses to further affect the desired optical and/or electronic tuning.

FIG. 2 is a diagram showing a sectional view of a stack **200** for an optoelectronic device according to a second embodiment of the present invention. The stack **200** is similar to the stack **100** of FIG. 1 except that the buffer region **112** does not comprise the one or more superlattices **130**.

FIG. 3 is a diagram showing a sectional view of an optoelectronic device **300** according to a third embodiment of the present invention. Similar to the stacks **100** and **200** of FIGS. 1 and 2, the optoelectronic device **300** comprises a substrate **110** on which a buffer layer **120** and a semiconductor structure **114** are formed. The semiconductor structure **114** comprises, in growth order, an n-type active region **140**, an i-type active region **150** and a p-type active region **160**. A p-type contact layer **170** is formed on the p-type active region **160** and a first contact layer **180** is formed on the p-type contact layer **170**.

In the embodiment shown in FIG. 3, the i-type active region **150**, the p-type active region **160**, p-type contact layer **170** and the first contact layer **180** form a mesa on the n-type active region **140**. The mesa shown in FIG. 3 has straight sidewalls. However, in alternative embodiments, the mesa can have angled side walls. The device **300** further comprises a second contact layer **382** formed on the n-type active region **140**. In preferred embodiments, the second contact layer **382** forms a ring or loop around the mesa. The second contact layer **382** enables a negative terminal of a voltage source to be connected to the n-type active region **130**. The device **300** further comprises a passivation layer **390** that covers the exposed or physically etched layers of the one or more superlattices. The passivation layer **390** is preferably made of a material having a wider band gap than the exposed or physically etched layers that it covers. The passivation layer **390** reduces current leakage between the layers of the one or more superlattices.

The device **300** can be operated as a vertically emissive device or a waveguide device. For example, in some embodiments, the optoelectronic device **300** can behave as a vertically emissive device with light out coupled from the interior of an electron-hole recombination region of the i-type active region **150** through the n-type active region **140** and the substrate **110**. In preferred embodiments, light propagating upwards (in the growth direction) in the optoelectronic device **300** is also retroreflected, for example, from the first contact layer **180**.

FIG. 4 is a diagram showing a sectional view of an optoelectronic device **400** according to a fourth embodiment of the present invention. The optoelectronic device **400** is similar to the optoelectronic device **300** of FIG. 3. However, the optoelectronic device comprises a first lateral contact **486** and a second lateral contact **484**.

The first lateral contact **486** extends partially into the p-type active region **160** from the first contact layer **180**. In preferred embodiments, the first lateral contact **486** is an annular shaped protrusion extending from the first contact layer **180** into in the p-type active region **160** and (where applicable) the p-type contact layer **170**. In some embodiments, the first lateral contact **486** is made from the same material as the first contact layer **180**.

The second lateral contact **484** extends partially into the n-type active region **140** from the second contact layer **482** formed on a surface of the n-type active region **140**. In preferred embodiments, the second lateral contact **484** is an annular shaped protrusion extending into in the n-type active region **140** from the second contact layer **382**. In some embodiments, the second lateral contact **484** is made from the same material as the second contact layer **382** to improve electrical conduction between the n-type active region **140** and the second contact layer **382**.

In preferred embodiments, the first lateral contact **486** and the second lateral contact **484** contact a plurality of narrower bandgap layers of the one or more superlattices in the semiconductor structure **114**, and therefore couple efficiently for both vertical transport of charge carriers perpendicular to the plane of the layers and parallel transport of charge carriers parallel to the plane of the layers. In general, carrier transport in the plane of the layers achieves higher mobility than carrier transport perpendicular to the plane of the layers. However, efficient transport perpendicular to the plane of the layers is achieved by using thin wider bandgap layers to promote quantum mechanical tunnelling. For example, in a superlattice comprising alternating layers of AlN and GaN, it is found that electron tunnelling between adjacent allowed energy states in each GaN layer is

enhanced when the interposing AlN layers have a thickness of less than or equal to 4 monolayers. Holes on the other hand, and in particular the heavy-holes, have a tendency to remain confined in their respective GaN layers and be effectively uncoupled by tunnelling through the AlN layers, which act as barriers, when the AlN layers have thicknesses of 2 monolayers or greater.

In preferred embodiments, the first lateral contact **486**, and the second lateral contact **484** improve electrical conductivity between the first contact layer **180** and the p-type active region **160**, and between the second contact layer **482** and the n-type active region **140**, respectively, by making use of a superior in-plane carrier transport compared to a vertical transport across the layer band discontinuities of the superlattice. The first lateral contact **484** and the second lateral contact **486** can be formed using post growth patterning and production of 3D electrical impurity regions to discrete depths.

FIG. **5** is a diagram showing a sectional view of an optoelectronic device **500** according to a fifth embodiment of the present invention. The optoelectronic device **500** is similar to the optoelectronic device **400** of FIG. **4**, except that the optoelectronic device **500** does not include a p-type contact layer **170** and the first lateral contact **486** is surrounded by an enhancement layer **588**, such as a layer of p-type GaN, between the first lateral contact **486** and the p-type active region **160**. The enhancement layer **588** can improve an Ohmic connection between the p-type active region **160** and the first contact layer **180**. The enhancement layer **588** can be created by selective area regrowth upon a patterned surface of the p-type active region **160**.

FIG. **6** is diagram showing a sectional view of an optoelectronic device **600** according to a sixth embodiment of the present invention. The optoelectronic device **600** is similar to the optoelectronic device **500** of FIG. **5**. However, the first contact layer **680** is annular shaped and a reflector layer **692** is provided to improve the out coupling of the optical energy generated within the semiconductor structure. The reflector layer **692** is positioned atop the optoelectronic device **600** to substantially retroreflect emitted light from the interior of the optoelectronic device **600**.

In preferred embodiments, the passivation layer **390** is also provided within the annulus formed by the first contact layer **680**, and the reflector **692** is formed atop of the passivation layer **390**. In alternative embodiments, the reflector **692** may be formed on top of the p-type active region **160**, or, if present, the p-type contact layer **170**.

FIG. **7** is a diagram showing a perspective view of an optoelectronic device **700** according to a seventh embodiment of the present invention. The optoelectronic device **700** is similar to the optoelectronic device **600** of FIG. **6**. However, the optoelectronic device **700** comprises a buffer region **130** and the passivation layer **390** is not shown. The first contact layer **680** and the reflector layer **692** are shown above the p-type active region **160** on the mesa. The second contact layer **382** is formed on the buffer region **130** as a ring around the mesa.

FIG. **8** is a diagram showing a sectional view of an optoelectronic device **800** according to an eighth embodiment of the present invention. The optoelectronic device **800** is similar to the optoelectronic device **600** of FIG. **6**. However, the optoelectronic device does not comprise the enhancement layer **588**.

As shown in FIG. **8**, upon application of an external voltage and current source between the first contact layer **680** and the second contact layer **382**, holes **802** are injected into the p-type active region and combine, for example at

point **808**, with electrons **804** generated in the n-type active region **140**. The injected electrons **804** and holes **802** recombine advantageously in the electron-hole recombination (EHR) region **809** that is substantially confined spatially within the i-type active region **150**. The EHR region **809** generates photons via electron-hole recombination with an energy and optical polarization of the photons dictated by the energy-momentum band structure of the one or more superlattices. As illustrated in FIG. **8**, the EHR emits photons **806A**, **806B**, **806C**, **806D**, in directions that can be classified as substantially in the plane of the layers or vertically parallel to the growth direction. Light can also propagate in other directions and can propagate in a non-trivial way within the structure. In general, light generated with a propagation vector that is substantially vertical and within an escape cone (determined by the angle of total internal reflection and thus the refractive index of the material) will be the major source of photons that can be out coupled vertically through the transparent substrate **110**. Photons **806A** are emitted in a generally vertical direction and in the same direction as the growth direction **101** shown in FIG. **1**. Photons **806B** are emitted in a generally vertical direction and in an opposite direction to the growth direction **101**. Photons **806C**, **806D** are emitted in a generally horizontal direction, parallel to the layers of the device, for example, parallel to the plane of the layers of the i-type active region **150**.

In the embodiment shown in FIG. **8**, some of the photons **806A** are reflected off the optical reflector **692** and exit the light emitting device **800** through the substrate **110**. It should be appreciated that with the addition of suitable mirrors (not shown) or an advantageous optical cavity and refractive index discontinuity between the substrate and i-type active region the device may therefore be modified to produce a microcavity LED or laser or a superluminescent LED. Superluminescence is found to improve the extraction efficiency of light by limiting the number of optical modes available for the generated light to couple into. This effective optical phase space compression improves selectivity of the device for advantageous vertical emission. An optical cavity can be formed using the total optical thickness formed by the buffer layer **120**, the n-type active region **140**, the i-type active region **150** and the p-type active region **160**. If the optical cavity is formed between the reflector **692** and the substrate **110** and the thickness of the optical cavity along the growth direction is less than or equal to one wavelength of the emission wavelength, then the cavity is a microcavity. Such a microcavity possesses the properties necessary to create superluminescence and stable wavelength operation imposed by the optical cavity mode wavelength. In some embodiments of the present invention, an emission wavelength from the EHR region **809** is equal to the lowest order wavelength cavity mode of the microcavity and superluminescence is achieved. A second optical reflector can also be included within the buffer region **112**. For example, a reflector comprising a superlattice having unit cells comprising elemental Al and AlN layers termed herein a metal-dielectric superlattice.

In some embodiments, a transparent region is provided adjacent to the buffer layer **120** and the substrate **110**, and the buffer layer **120** is transparent to optical energy emitted from the device. The optical energy is coupled externally through the transparent region, the buffer layer **120** and the substrate **110**. Photons **806C**, **806D** are emitted in a generally horizontal direction, parallel to the layers of the device, for example, parallel to the plane of the layers of the p-type active region **160**.

In some embodiments, the optoelectronic device emits light having a substantially transverse magnetic optical polarization with respect to the growth direction. The optoelectronic device operates as an optical waveguide with light spatially generated and confined along a direction substantially parallel to the plane of the one or more layers of the unit cells of the one or more superlattices of the semiconductor structure.

In some embodiments, the optoelectronic device emits light having a substantially transverse electric optical polarization with respect to the growth direction. The optoelectronic device operates as a vertically emitting cavity device with light spatially generated and confined along a direction substantially perpendicular to the plane of the one or more layers of the unit cells of the one or more superlattices of the semiconductor structure. The vertically emitting cavity device has a vertical cavity disposed substantially along the growth direction and formed using metallic reflectors spatially disposed along one or more portions of the semiconductor structure. The reflectors can be made from a high optical reflectance metal. The cavity is defined by the optical length between the reflectors being less than or equal to a wavelength of the light emitted by the device. The emission wavelength of the optoelectronic device is determined by the optical emission energy of the one or more superlattices comprising the semiconductor structure and optical cavity modes determined by the vertical cavity

FIG. 9 is a graph 900 of spatial energy levels in the conduction band and the valence band with respect to a distance along the growth direction  $z$  for an optoelectronic device, according to an embodiment of the present invention. In this embodiment, a single superlattice comprises the n-type active region 140, the i-type active region 150 and the p-type active region 160 of the optoelectronic device. Each unit cell of the superlattice comprises a first layer formed of two monolayers of AlN and a second layer formed of one monolayer of GaN. The superlattice comprises 25 unit cells in each of the n-type active region 140, the i-type active region 150 and the p-type active region 160. The superlattice is deposited on a c-plane with a metal-polar crystal growth oriented parallel to the growth direction. A p-type contact layer made of p-GaN is deposited on the p-type active region 160. A first contact layer made of an idealized ohmic metal M is located on the p-GaN contact layer and a second contact layer made of an idealized ohmic metal M is located on the n-type active region 140.

The y-axis of FIG. 9 is the energy level in eV relative to the Fermi energy, and the x-axis is the distance in nanometres (nm) along the growth direction 101 from the base of the substrate. The positions of the n-type active region 140, the i-type active region 150 and the p-type active region 160 and other regions/layers of the device are shown above the x-axis. Trace 910 is the zone centre (i.e.,  $k=0$ ) energy in the conduction band; the troughs are due to GaN, and the peaks are due to AlN. Graph 900 shows in trace 910 that the conduction band energy  $E_c^{k=0}(z)$  is close to the Fermi energy in the n-type active region 140 with the troughs of the conduction band energy  $E_c^{k=0}(z)$  below the Fermi energy. This provides a highly activated n-type active region. Trace 920 is energy in the valence band; the troughs are due to AlN, and peaks are due to GaN. Graph 900 shows in trace 920 that the valence band energy  $E_{HH}^{k=0}(z)$  is close to the Fermi energy in the p-type active region 160 with the peaks of the valence band energy  $E_{HH}^{k=0}(z)$  above the Fermi energy. This provides a highly activated p-type active

region. The metal polar oriented growth results in the pyroelectric and piezoelectric charges at each AlN/GaN and GaN/AlN heterojunction.

A spatial wavefunction is a probability amplitude in quantum mechanics that describes the quantum state of a particle and how it behaves. FIG. 10 is a graph 1000 showing the quantized lowest energy electron spatial wavefunctions  $\Psi_c^{n=1}(i,z)$  with respect to a distance  $z$  along the growth direction for the optoelectronic device described with reference to FIG. 9. The index  $i$  represents the distinct wavefunctions. Each quantized wavefunction is plotted at the corresponding allowed quantized eigenenergy within the energy band structure. A non-zero wavefunction probability above the respective quantized energy level indicates a finite probability of localizing an electron in the associated spatial region. The conduction band edge energy  $E_c^{k=0}(z)$  is shown for reference.

It is evident from graph 1000 that the electron wavefunctions are delocalized over a large number of unit cells. This is indicative of high coupled GaN potential wells. The thin AlN barriers (2 monolayers) allow efficient quantum mechanical tunnelling and thus form energy manifolds spatially confined within the n-type and p-type active regions. An electron injected into the n-type active region would be efficiently transported along the growth direction toward the i-type active region. The allowed lowest energy wavefunctions within the i-type active region are more confined than within the n-type or p-type active regions, as is evidenced by the more localized wavefunctions in the i-type active region. The small thickness of the unit cells forces the quantized energy levels to be relatively close to the AlN conduction band edge and thus under the influence of a large depletion electric field generated across the i-type active region breaks the coupling between adjacent neighbouring GaN potential minima. As a result the electron wavefunctions in the i-type active region are not strongly confined to their respective GaN potential minima.

FIG. 11 is a graph 1100 showing the quantized lowest energy heavy hole spatial wavefunctions  $\Psi_{HH}^{n=1}(j,z)$  with respect to a distance along the growth direction for the optoelectronic device described with reference to FIG. 9. The heavy hole zone centre valence band energy  $E_{HH}^{k=0}(z)$  is shown for reference. The group III metal nitride materials have a unique valence band structure comprising an energy momentum dispersion that has three distinct bands, namely, the heavy-hole (HH), light-hole (LH) and crystal field split (CF) bands. At zone centre, the superlattice has the heavy-hole band which is the lowest energy of the three, that is,  $E_{HH}^{k=0} < E_{LH}^{k=0} < E_{CH}^{k=0}$ . For optical processes of interest herein it is sufficient to describe the HH band only. In the graph 1100, it is evident that there is substantial spatial delocalization of heavy-hole wavefunctions  $\Psi_{HH}^{n=1}(j,z)$  within the p-type active region, whereas they are tightly confined to the GaN potential minima within the i-type active region. Again the built-in depletion electric field within the device breaks the coupling within the i-type active region.

FIG. 12 is a graph 1200 showing the spatial overlap integral of the conduction and HH wavefunctions. The overlap integral is essentially the product of the electron spatial wavefunctions  $\Psi_c^{n=1}(i,z)$  of FIG. 10 with each of the heavy hole spatial wavefunctions  $\Psi_{HH}^{n=1}(j,z)$  of FIG. 11 with respect to a distance along the growth direction for the optoelectronic device described with reference to FIG. 9. It can be seen from graph 1200 that the probability that an electron and a hole are present at the same location is higher in the i-type active region 150 than the n-type active region

140 and the p-type active region 160. Hence emission is more likely to occur from the i-type active region 150 than the n-type active region 140 and the p-type active region 160 of the optoelectronic device.

FIG. 13 is a graph 1300 showing the overlap integral of the electron spatial wavefunctions  $\Psi_c^{n=1}(i,z)$  and the heavy hole spatial wavefunctions  $\Psi_{HH}^{n=1}(j,z)$  with respect to a combined transition energy between the corresponding electron and hole quantized energy levels for the optoelectronic device described with reference to FIG. 9. The discrete plot of FIG. 13 shows the energy spectrum of allowed optical transitions between the lowest  $n=1$  quantized electron states and the  $n=1$  HH states within the entire semiconductor structure. The graph 1300 therefore shows the device is capable of emitting with a lowest energy optical emission of about 5.3 eV. The width of the emission spectrum in FIG. 13 is indicative of the miniband widths of quantized energy levels throughout the device.

FIG. 14 is a graph 1400 showing an emitted luminance versus wavelength for the optoelectronic device described with reference to FIG. 9. The discrete overlap integrals of FIG. 13 are homogeneously broadened in energy to simulate thermal variations anticipated at room temperature. The sum of individual oscillator strength contributions are plotted as a function of wavelength for two choices of broadening parameters. The longest wavelength and sharpest transition is attributed to the lowest energy heavy-hole exciton experimentally observable. As shown in FIG. 14, the wavelength of maximum intensity is at approximately 230 nm corresponding to the lowest energy transition between the  $n=1$  quantized electron and hole wavefunctions. Reference to FIG. 12 indicates that a substantial portion of the light generated will be from a region near the i-type active region and p-type active region interface. The shaded region of FIG. 14 shows the spectral region populated by the p-type and n-type active regions which will have states occupied and thus not available for optical recombination process. Furthermore, the actual emission energy is due to the lowest order exciton annihilation. An exciton is an intermediate particle comprising a bound electron-hole pair that is spatially confined to enhance the electrostatic binding energy. The  $n=1$  exciton binding energy ( $E_X^{n=1}$ ) in an AlN/GaN superlattice is of the order of 50-60 meV and is due to the electrostatic attraction of the  $n=1$  electron and  $n=1$  HH wavefunctions. In general, the emission energy of a photon, emitted from the  $n=1$  exciton  $E_\gamma^{n=1}$ , is given by  $E_\gamma^{n=1} = E_C^{n=1} - E_{HH}^{n=1} - E_X^{n=1}$ , where the exciton binding energy reduces the observed emission energy.

FIG. 15 is a graph 1500 of spatial energy levels in the conduction band and the valence band with respect to a distance along the growth direction  $z$  for an optoelectronic device, according to another embodiment of the present invention. In this embodiment, superlattice forming the n-type active region 140 and the p-type active region 160 of the device are the same as for the optoelectronic device of FIG. 9. However, in the i-type active region 150 the first layer in each unit cell is formed of 4 monolayers of AlN and the second layer in each unit cell is formed of 2 monolayers of GaN. The p-type and n-type regions are formed using impurity doped superlattices with a first layer formed of 2 monolayers of AlN and a second layer formed of 1 monolayer of GaN. The doped regions are therefore transparent to the  $n=1$  exciton formed in the intrinsic region. While the period or thickness of the unit cells changes between the n-type and p-type active regions and the i-type active region, the unit cells in each region have the same average alloy content. That is, the Al fraction in the unit cells is constant.

There are 25 repetitions of the unit cell in each region. It is found that a higher number of unit cell repetitions can also be used. The average alloy content of a simple unit cell comprising two compositions, such as, a GaN layer of thickness  $t_{GaN}$  and AlN layer of thickness  $t_{AlN}$ , is given by  $x_{ave} = t_{AlN} / (t_{AlN} + t_{GaN})$ , where the  $x_{ave}$  represents the effective Al fraction of the pair in the unit cell. In alternative embodiments, the unit cells can comprise three or more AlGaIn compositions and in such embodiments the effective alloy content can be similarly determined. The average alloy content of other layer compositions comprising binary, ternary and quaternary materials can be defined according to one or more elemental constituents. For example, the Al fraction in a tri-layered unit cell comprising the triple layers of AlN/Al<sub>x</sub>Ga<sub>1-x</sub>N/GaN or AlN/Al<sub>x</sub>Ga<sub>1-x</sub>N/Al<sub>y</sub>In<sub>z</sub>Ga<sub>1-y-z</sub>N can be determined. An optional p-type GaN Ohmic contact layer is included on the p-type active region. Ohmic metal contacts provided on the n-type active region and the optional p-type GaN Ohmic contact layer. The energy band structure is shown with zero external electrical bias applied between the Ohmic metal contacts.

The y-axis of FIG. 15 is the energy level in eV relative to the Fermi energy, and the x-axis is distance in nanometres (nm) along the growth direction from the base of the substrate. The positions of the n-type active region 140, the i-type active region 150 and the p-type active region 160 of the device are shown above the x-axis. Trace 1510 is energy in the conduction band; the troughs are due to GaN, and the peaks are due to AlN. The AlN layer and GaN layer in the unit cells forms a type-I superlattice, wherein the GaN conduction band is lower in energy than the AlN conduction band edge and the GaN valence band is higher in energy than the AlN valence band edge. That is, the AlN layer presents a potential barrier for both electrons and holes in the GaN layer. Trace 1520 is energy in the valence band; the troughs are due to AlN, and peaks are due to GaN. In particular, the heavy-hole valence band edge is shown. FIG. 15 shows that the period and amplitude of the peaks and troughs in traces 1510 and 1520 has increased in the i-type active region 150. The larger layer thicknesses of both the GaN and AlN layers in the unit cells in the i-type active region generates a larger built-in electric field across each due to the spontaneous and piezoelectric fields of the metal-polar heterointerfaces. This effect is particularly unique to polar wurtzite crystals. Again, the device of FIG. 15 is contacted by ideal metal contacts M and a p-GaN contact layer connects the p-type active region 160 to one of the metal contacts. Flat band conditions are shown, that is, zero external applied bias between both contacts, and thus the Fermi energy is continuous throughout the structure along the growth direction.

FIG. 16 is a graph 1600 showing the quantized lowest energy ( $n_{sz}=1$ ) electron spatial wavefunctions  $\Psi_c^{n=1}(i,z)$  with respect to a distance  $z$  along the growth direction for the optoelectronic device described with reference to FIG. 15. The conduction band edge energy  $E_c^{k=0}(z)$  is shown for reference.

The electron wavefunctions are clearly spread out across a large number of adjacent and neighbouring unit cells due to the thin AlN tunnel barriers in both the n-type and p-type active region. The larger unit cell period of the i-type active region shows a pronounced localization of the electron wavefunctions to at most a nearest neighbour penetration. There are no leaky wavefunctions outside of the superlattice within the forbidden gap of the i-type active region as was observed in the structure of FIG. 10. Therefore, the electrons injected from the n-type active region would undergo efficient transport through the n-type active region miniband

and into the i-type active region. Electrons that are captured in the lowest energy quantized wavefunctions in the i-type active region are then available for recombination with a spatially coincident  $n_{SZ}=1$  heavy-hole in the valence band.

FIG. 17 is a graph 1700 showing the quantized lowest energy heavy hole spatial wavefunctions  $\Psi_{HH}^{n=1}(j,z)$  with respect to a distance along the growth direction for the optoelectronic device described with reference to FIG. 15. The heavy hole valence band energy edge  $E_{HH}^{k=0}(z)$  is shown for reference. Once again, as observed in FIG. 11, the heavy hole wavefunctions are substantially delocalized across several unit cells in the n-type and p-type active regions. The i-type active region has a larger unit cell period than the n-type and p-type active regions, and the same average Al fraction within the unit cell as the p-type and n-type superlattice regions. Again, the GaN potential minima generate the lowest energy valence states as belonging to heavy hole states.

FIG. 18 is a graph 1800 showing the spatial overlap integral between the lowest energy quantized electron and heavy hole valence wavefunction states. The overlap integral is substantially the product of the quantized electron spatial wavefunctions  $\Psi_c^{n=1}(i,z)$  of FIG. 16 and the heavy hole spatial wavefunctions  $\Psi_{HH}^{n=1}(j,z)$  with respect to a distance along the growth direction for the optoelectronic device described with reference to FIG. 15. The strength of the overlap integral is proportional to the oscillator strength of the specific transition. In general, if the electron and hole wavefunction probabilities coincide spatially, then there is a finite probability for an electron-hole recombination event. The energy width of the allowed optical transitions is indicative of quantum mechanical tunnelling between GaN layers through a thin AlN barrier layer. The intrinsic region has thicker AlN barriers and thus reduced conduction band tunnelling. The oscillator strength of the intrinsic region is shown to be stronger compared to the n-type and p-type regions. It can be seen from graph 1800 that the probability that an electron and a hole are present at the same location is higher in the i-type active region 150 than the n-type active region 140 and the p-type active region 160. Hence optical emission due to electron and heavy hole recombination is more likely to occur from the i-type active region 150 than the n-type active region 140 and the p-type active region 160 of the optoelectronic device. Graph 1800 also shows that probability of emission from the i-type active region 150 is higher for the optoelectronic device described with reference to FIG. 15 than for the optoelectronic device described with reference to FIG. 9.

FIG. 19 is a graph 1900 showing the overlap integral of the electron spatial wavefunction  $\Psi_c^{n=1}(i,z)$  and the heavy hole spatial wavefunction  $\Psi_{HH}^{n=1}(j,z)$  with respect to a combined transition energy of the corresponding lowest energy quantized electrons and heavy holes for the optoelectronic device described with reference to FIG. 15.

The lowest energy optical transition due to the  $n=1$  exciton is therefore due to recombination originating in the i-type active region which has a larger period than both the p-type and n-type active regions. The emission energy of the i-type active region is therefore selected to be at a longer wavelength than the lowest energy absorption of both the n-type and p-type active regions. This enables the generated photons within the i-type active region to propagate without absorption (and thus loss) within the cladding regions, i.e. the p-type and n-type active regions, and furthermore enables the light to be extracted from the interior of the device.

This represents a preferred implementation of the present invention wherein the emission and absorption properties of the regions of the semiconductor structure or the device are controlled by selection of the respective superlattice unit cell periods. Furthermore, the average alloy content is kept constant throughout the superlattice regions and thus the in-plane lattice constant of each unit cell is matched and no accumulation of strain energy is witnessed as a function of growth direction. This enables high crystal quality superlattice stacks to be realized. Furthermore, there is no discontinuity in the built-in electric fields due to polarization charges within the structure, enabling the stack to be polarization stabilized.

FIG. 20 is a graph 2000 showing an emitted luminance versus wavelength for the optoelectronic device described with reference to FIG. 15. The discrete overlap integrals of FIG. 19 are homogeneously broadened in energy to simulate thermal variations anticipated at room temperature. The sum of individual oscillator strength contributions are plotted as a function of wavelength for two choices of broadening parameters. The longest wavelength and sharpest transition is attributed to the lowest energy  $n=1$  heavy-hole exciton and is spatially confined in the intrinsic region. As shown in FIG. 20, the wavelength of maximum intensity is at approximately 247 nm, which is longer than the wavelength of maximum intensity in FIG. 14 for the optoelectronic device described with reference to FIG. 9.

The optoelectronic devices of FIGS. 9 and 15 differ only in the choice of period for the one or more superlattices in the i-type active region. All the unit cells of all the one or more superlattices in the semiconductor structure are selected for these examples to have a fixed average alloy content. The average alloy content is selected to be defined as the Al fraction of the unit cell. For example, a unit cell comprising 1 monolayer of GaN and 2 monolayers of AlN has an Al fraction  $x_{ave}=\frac{2}{3}$ , and for a unit cell with 2 monolayers of GaN and 4 monolayers of AlN equally has an Al fraction  $x_{ave}=\frac{4}{6}=\frac{2}{3}$ . Again, for simplicity only, 25 unit cell repetitions are used in each region. That is, not only does the average Al fraction of the unit cell determine an equivalent ordered ternary alloy composition of the form of  $Al_{x_{ave}}Ga_{1-x_{ave}}N$ , but the period defines an optical emission energy for the said unit cell.

FIG. 21 is a graph 2100 of the spatially dependent energy levels in the conduction band and the valence band with respect to a distance along the growth direction for an optoelectronic device, according to another embodiment of the present invention. It is understood that reference to the zone centre ( $\underline{k}=0$ ) conduction and heavy hole valence bands are sufficient to describe the device operation. In this embodiment, one or more superlattices forming the n-type active region, the i-type active region and the p-type active region are similarly composed of bilayered unit cells having an AlN layer and a GaN layer as in the case of the optoelectronic devices described with reference to FIGS. 9 and 15. The effective Al fraction in the case of FIG. 21 is however selected to have a lower Al fraction of  $x_{ave}=0.5$ . In the i-type active region 150, the first layer in each unit cell is formed of 3 monolayers of AlN and the second layer in each unit cell is formed of 3 monolayers of GaN. Both the n-type and p-type active regions are selected to also have  $x_{ave}=0.5$  but designed to have a larger optical energy at the onset of absorption to render them substantially transparent to the optical emission energy generated by the i-type active region. The p-type and n-type active regions are selected to have unit cells comprising only 2 monolayers of GaN and 2 monolayers of AlN. The thinner layers of GaN results in an

increase in the energy separation between the lowest quantized energy levels in the conduction and valence bands. The p-type and n-type regions are formed using impurity doped superlattices.

The y-axis of FIG. 21 is the energy level band diagram (in units of electron volts, eV) relative to the Fermi energy, and the x-axis is distance in nanometres (nm) along the growth direction from the base of the substrate. The spatial positions and extent of the n-type active region 140, the i-type active region 150 and the p-type active region 160 of the optoelectronic device are shown above the x-axis. Trace 2110 is the zone centre (or minimum) energy in the conduction band; the troughs are due to GaN, and the peaks are due to AlN. Careful inspection shows that the built-in pyroelectric and piezoelectric fields for the metal polar structure are different in the i-type active region to both the n-type and p-type active regions. This is due to the larger layer thicknesses of GaN and AlN in the i-type active region. Trace 2120 is spatial energy modulation in the valence band; the troughs are due to AlN, and peaks are due to GaN. FIG. 21 shows that the period of the unit cell (shown as the peaks and troughs) in the i-type active region 150 in traces 2110 and 2120 is roughly the same as the unit cell period shown in traces 1510 and 1520 shown in FIG. 15. However, the duty cycle (i.e. the relative GaN and AlN layer thickness within the unit cell) has changed. Again, the device is selected to have p-type and n-type active regions which are substantially transparent to the emission wavelength of the i-type active region.

FIG. 22 is a graph 2200 showing the lowest energy quantized electron spatial wavefunctions  $\Psi_c^{n=1}(i,z)$  with respect to a distance along the growth direction for the optoelectronic device described with reference to FIG. 21. The zone centre ( $k=0$ ) conduction band energy  $E_c^{k=0}(z)$  is shown for reference. The n-type and p-type spatial regions exhibit highly coupled wavefunctions and form an  $n=1$  superlattice miniband. The intrinsic region shows electron wavefunctions coupled across only nearest neighbour potential wells by virtue of the built-in depletion field and the thicker AlN barriers.

FIG. 23 is a graph 2300 showing lowest energy quantized heavy hole spatial wavefunctions  $\Psi_{HH}^{n=1}(j,z)$  with respect to a distance along the growth direction for the optoelectronic device described with reference to FIG. 21. The zone centre ( $k=0$ ) heavy hole valence band energy  $E_{HH}^{k=0}(z)$  is shown for reference. The heavy-hole wavefunctions in the p-type and n-type regions are delocalized over a large number of neighbouring potential wells. Conversely, the heavy-hole wavefunctions in the i-type active region are highly localized to their respective potential well by virtue of the larger AlN barrier width and built-in depletion field.

FIG. 24 is a graph 2400 showing the spatial overlap integral of the electron and heavy hole wavefunctions. The overlap integral is substantially the product of the electron spatial wavefunctions  $\Psi_c^{n=1}(i,z)$  of FIG. 22 and the heavy hole spatial wavefunctions  $\Psi_{HH}^{n=1}(j,z)$  of FIG. 23 with respect to a distance along the growth direction for the optoelectronic device described with reference to FIG. 21. The overlap integral represents the oscillator strength for the respective direct electron & heavy-hole transition. The energy width of the allowed optical transitions is indicative of quantum mechanical tunnelling between GaN layers through an AlN barrier layer. The i-type active region has thicker AlN barriers and thus reduced conduction band tunnelling. The oscillator strength of the i-type active region is shown to be stronger compared to the n-type and p-type active regions. It can be seen from graph 2400 that the

probability that an electron and a hole are present at the same spatial location is higher in the i-type active region 150 than both the n-type active region 140 and the p-type active region 160. Hence emission is more likely to occur from the i-type active region 150 than the n-type active region 140 and the p-type active region 160 of the optoelectronic device. Graph 2400 also shows that probability of emission from the n-type active region 140 and the p-type active region 160 is lower for the optoelectronic device described with reference to FIG. 21 than for the optoelectronic devices described with reference to FIGS. 9 and 15.

FIG. 25 is a graph 2500 showing the overlap integral of the electron spatial wavefunctions  $\Psi_c^{n=1}(i,z)$  and the heavy hole spatial wavefunctions  $\Psi_{HH}^{n=1}(j,z)$  with respect to a combined transition energy of the corresponding lowest energy quantized electrons and holes for the optoelectronic device described with reference to FIG. 21. A stronger oscillator strength of the lowest energy transitions in the i-type active region compared to the n-type and p-type active regions is due to electron and heavy-hole recombination in the i-type active region.

FIG. 26 is a graph 2600 showing an emitted luminance versus wavelength for the optoelectronic device described with reference to FIG. 21. The discrete overlap integrals of FIG. 25 are homogeneously broadened in energy to simulate thermal variations anticipated at room temperature. The sum of individual oscillator strength contributions are plotted as a function of wavelength for two choices of broadening parameters. The longest wavelength and sharpest transition is attributed to the lowest energy  $n=1$  heavy-hole exciton and is spatially confined in the i-type active region As shown in FIG. 26, the wavelength of maximum intensity is at approximately 262 nm, which is substantially longer than the wavelengths of maximum intensity in FIGS. 14 and 20 for the optoelectronic devices described with reference to FIGS. 9 and 15 respectively.

The tuning of the emission wavelength and the other aspects of the device is discussed in further detail below.

The present invention utilizes a semiconductor structure that is preferably crystalline and more preferably formed as a single crystal atomic structure. In a preferred embodiment, for emission of ultraviolet and deep ultraviolet light, the semiconductor structure has a wurtzite crystal structure composed of ionic bonds and formed from one or more semiconductors, such as, group III metal nitride (III-N) semiconductors or group II metal oxide (II-VI) semiconductors.

FIG. 27A shows a wurtzite crystal structure 2700 for a group III metal nitride semiconductor. The wurtzite crystal structure includes metal crystal sites 2715 and nitrogen atom sites 2720. The polarity of the crystal bonds along the miller notation  $[h\ k\ i\ l]=[0\ 0\ 0\ 1]$  direction 2750 is shown to be of a nitrogen-polar crystal orientation having a nitrogen polar bond 2725. The structure can be inverted by mirror reflection about 2760 and becomes a metal-polar oriented crystal. If the crystal axis 2750 is taken as the growth direction  $[0\ 0\ 0\ 1]$  then the c-plane  $(0\ 0\ 0\ 1)$  is identified as the plane labelled 2730. The horizontal crystal axis 2760 is one of the high symmetry slices through the wurtzite crystal having  $[1\ 1\ -2\ 0]$  direction.

FIG. 27B shows a view of the c-plane 2730 with the metal atoms terminating the surface. Nitrogen atom surface terminations of the c-plane are also possible. The crystal directions 2760 and 2780 represent in miller notation the  $[1\ 1\ -2\ 0]$  and  $[0\ 0\ 1\ -1]$  directions, respectively. Abrupt surface terminations are further subject to surface reconstructions of lower symmetry bond patterns. These surface

reconstructions minimize the growing surface energy, but ultimately form substantially idealized crystal structure within the bulk of the layer when the reconstructed surface is then overgrown with further material in the wurtzite crystal structure. The ideal metal terminated surface exhibits the hexagonal c-plane crystal cell identified as the hexagon **2785** having equal sides of in-plane lattice constant **2790**. The crystal fundamental repeating unit is then characterized by a wurtzite cell parameterized as the lattice constant *a*, labelled as **2790**, and the hexagonal column of height *c*, labelled as **2705** or **2710** in FIG. **27A**. For example, a strain free AlN epilayer would have *a*=4.982 Å and *c*=5.185 Å. One monolayer (1ML) is defined herein as equal to 1ML=*c*/2, for film deposited upon a c-plane.

FIG. **27C** shows perspective view of an AlN wurtzite crystal **2770** oriented along the c-axis **2750** and further exposing an Al atom surface. The Al terminated surface lies wholly in the c-plane **2730** with the wurtzite crystal unit cell defined by the hexagon **2760**. The vertical thickness along the direction **2750** shows four monolayers of AlN material and the associated crystal orientations. For example, in some embodiments, a c-plane oriented epitaxial deposition upon a substrate can include depositing with high uniformity a plurality of monolayered films which extend laterally in directions **2760** and **2780**, spanning the substrate surface area.

FIG. **28** is a chart **2800** showing the preferred range of layered thicknesses for an example superlattice. The unit cells of the superlattice comprise two layers formed exclusively of binary compositions of GaN and AlN, respectively. For example, the superlattice is formed of wurtzite GaN and AlN films deposited upon a c-plane as shown schematically for an idealized spatial portion in FIG. **27C**. The chart **2800** of FIG. **28** shows the columns tabulated in terms AlN thickness as a whole number of monolayers *N* along a c-axis, and the physical thickness in units of Angstroms (n.b., 1 Å=0.1 nm). Similarly, the rows tabulate in terms of whole monolayers *M* of GaN with the table entries calculating the unit cell period thickness:  $\Lambda_{SL} = M \cdot (1ML \text{ GaN}) + N \cdot (1ML \text{ AlN}) = M \cdot c_{GaN} / 2 + N \cdot c_{AlN} / 2$ .

A superlattice having a unit cell which repeats  $N_p$  times and has a constant Al fraction along a growth direction can be defined as a GaN and AlN pair having *M* and *N* monolayers, written for convenience herein as M:N.

FIG. **29** shows a crystal lattice structure of one unit cell of a 4:4 superlattice wherein the 4 monolayers of GaN **2940** are deposited epitaxially upon 4 monolayers of AlN **2930** along a c-axis **2750** which defines a growth direction. The Al atoms sites are shown as the large white spheres **2905**, the Ga atom sites are depicted as the large grey spheres **2920** and the nitrogen atom sites are shown as the small black spheres **2915** and **2925**. The AlN/GaN heterointerface **2935** can be abrupt having purely Ga or Al metal terminations or can be an intermixed interface having random distribution of Ga and Al atoms in the plane **2935**. The vertical height of the GaN epilayer **2940** is larger than the lower AlN epilayer **2930** by virtue of elastic deformation of the crystal unit cells. A free standing superlattice unit cell **2900** would ideally exhibit no interfacial dislocations (namely, misfit dislocations) and would have the AlN layer in state of in-plane tensile strain and the GaN epilayer in a state of in-plane compressive strain. The elastically deformed dissimilar epilayers are ideally deposited with a thickness along a c-axis **2750** that is below the critical layer thickness (CLT). The CLT is the maximum thickness that a lattice mismatched material can be deposited upon an underlying crystal without forming misfit dislocations. All of the M:N combinations

disclosed in chart **2800** of FIG. **28** are representative of such superlattice unit cells which are deposited below the CLT of each material. Note, the CLT can be theoretically calculated and experimentally determined. For example, direct in-situ measurements using reflection high energy electron diffraction (RHEED) during heteroepitaxy in MBE can determine the CLT with great accuracy.

FIG. **30** is a chart **3000** showing further possible implementations of unit cells formed by using on GaN and AlN materials deposited along a c-axis as defined herein. Chart **3000** defines fractional monolayer pairs of M:N with table entries showing the unit cell thickness  $\Lambda_{SL}$ . These unit cell thicknesses can be applied to deep ultraviolet emitters using group III metal nitride semiconductors. It is also found that other material compositions can be used and more than two compositions comprising a superlattice unit cell are applicable.

FIG. **31** shows a graph **3100** of an equilibrium in-plane lattice constant  $a_{||}^{SL}$  of a superlattice, constructed with unit cells having only a GaN and an AlN layer. The graph **3100** shows the calculated in plane lattice constant  $a_{||}^{SL}$  for a given selection of *M* monolayers of GaN and *N* monolayers of AlN in each unit cell. Each curve is parameterized by a distinct choice of *N* monolayers of AlN. The curves of graph **3100** can be used directly to design a superlattice LED comprising different unit cell M:N pairs and is discussed hereafter.

FIG. **32** shows schematically the atomic forces present in a structure **3200** comprising two unit cells **3270** and **3280**. Each unit cell comprises two layers and each of the two layers is formed of a dissimilar material, for example, first layers **3230** and **3250** can be GaN layers and second layers **3240** and **3260** can be AlN layers. The layers are formed by epitaxial deposition of crystals, which are elastically deformed due to the dissimilar crystal lattice constants in each adjacent layer. If the structure is deposited upon a c-plane, then the GaN layers **3230** and **3250** are subject to compressive in-plane stress **3220** and the AlN layers **3240** and **3260** have an induced tensile in-plane strain **3210**. Such a superlattice formed using lattice mismatched materials with each layer of each unit cell being formed with thickness below the CLT can achieve high crystalline perfection when formed with a sufficient number of periods. For example, using GaN and AlN materials only, a superlattice according to the teaching of the present invention is formed on a bulk-like c-plane AlN surface, a (0001)-oriented Sapphire surface, or another suitable surface. After approximately 10 to 100 periods of superlattice growth the final unit cells attain idealized free-standing in-plane lattice constants  $a_{||}^{SL}$ . This is one example method of forming a superlattice buffer **130** as discussed in relation to FIG. **1**.

In some embodiments of the present invention, each superlattice in the semiconductor structure has a distinct configuration that achieves a selected optical and electronic specification.

Experiments show that keeping an average alloy content in each unit cell constant along the superlattice is equivalent to keeping the average in-plane lattice constant of the unit cell  $a_{||}^{SL}$  constant. Experiments also show that the thickness of the unit cell can then be selected to achieve a desired optical and electrical specification. This enables a plurality of distinct superlattices to have a common effective in-plane unit cell lattice constant and thus enables the advantageous management of strain along a growth direction.

FIGS. **33** and **34** show graphs **3300** and **3400** of the equilibrium in-plane lattice constant  $a_{||}^{SL}$  of a superlattice, constructed with unit cells having only a GaN and an AlN layer. The graphs **3300** and **3400** show the calculated in

plane lattice constant  $a_{\parallel}^{SL}$  for a given selection of M monolayers of GaN and N monolayers of AlN in each unit cell. Each curve is parameterized by a distinct choice of N monolayers of AlN. Black dots are provided in each graph to show unit cell configurations having the same average alloy content. The black dots shown in the graph **3300** of FIG. **33** include M:N combinations where M=N and thus an effective Al fraction of  $x_{ave}^{SL}=1/2$  is achieved. The black dots in graph **3400** in FIG. **34** include M:N combinations where N=2M and thus a  $x_{ave}^{SL}=2/3$ .

The graphs of FIGS. **33** and **34** can be particularly useful for designing semiconductor structures having superlattices with unit cells exclusively built from GaN and AlN material combinations deposited along a c-axis and having wurtzite crystal structure.

FIG. **35** shows a graph **3500** of a calculated portion of the energy band structure of a  $N_p=100$  period superlattice comprising a M:N=5:5 unit cell that is repeated along a growth direction z. The spatial variation of the conduction band edge **3520** and heavy hole valence band edge **3550** are shown along with the quantized energy and spatially confined carrier wavefunctions **3510** and **3560**. GaN and AlN layers are selected from thicknesses which preserve the CLT of each of the respective layers, as shown in FIG. **30**. FIG. **35** shows that the electron wavefunctions **3510** exhibit a strong tendency for quantum mechanical tunnelling **3570** through the AlN barriers, whereas the heavy hole wavefunctions **3560** are tightly localized within their respective GaN potential minima.

FIG. **36** shows a superlattice **3600** used to simulate a semi-infinite number of periods of a superlattice of constant unit cell length and composition. In the superlattice, the unit cells have a constant length and composition. However, the first GaN layer **3605** is split in half and added to the end **3610** of the superlattice. Applying periodic boundary conditions for the wavefunctions thus simulates a semi-infinite number of periods, while investigating the interacting property of the base 99 unit cells **3620**. Using a finite element method and full k.p theory the wavefunctions are calculated along with the quantized energies of the lowest lying superlattice states. As described earlier, the optical emission spectrum is calculated from the overlap integrals and energy separation between the lowest energy (n=1) conduction band states and the n=1 heavy hole states.

FIGS. **37**, **38**, **39**, **40** and **41** show graphs of the transverse electric (TE) optical emission spectra of superlattices having  $x_{ave}^{SL}=2/3$  and M:N configurations of 1:2, 2:4, 3:6, 4:8 and 5:10, respectively. Each of the graphs shows four curves corresponding to the total emission and emission due to a particular valence band type (namely, HH, LH or CH) with an allowed conduction state. As discussed previously, a desired lowest energy emission is for a transition between an allowed conduction band state and a heavy-hole state, which satisfies the criteria for vertical emission parallel to c-axis and or growth direction.

FIG. **37** shows a graph **3700** of the emission spectrum of a 1:2 superlattice for the lowest energy transition of the n=1 conduction states and the n=1 heavy hole states ( $E_C^{n=1}-E_{HH}^{n=1}$ ) **3705**, the lowest energy transition of the n=1 conduction states and the n=1 crystal field split states ( $E_C^{n=1}-E_{CH}^{n=1}$ ) **3710**, and the lowest energy transition of the n=1 conduction states and the n=1 light hole states ( $E_C^{n=1}-E_{LH}^{n=1}$ ) **3715**. Curve **3720** shows the total spectrum that is observable. The large energy width of the emission peaks is fundamentally due to the large coupling between nearest neighbour GaN potential minima and thus the for-

mation of wide energy width minibands in both the conduction and respective valence bands.

FIG. **38** shows a graph **3800** of the emission spectrum of a 2:4 superlattice for the lowest energy transition of the n=1 conduction states and the n=1 heavy hole states ( $E_C^{n=1}-E_{HH}^{n=1}$ ) **3805**, the lowest energy transition of the n=1 conduction states and the n=1 crystal field split states ( $E_C^{n=1}-E_{CH}^{n=1}$ ) **3810**, and the lowest energy transition of the n=1 conduction states and the n=1 light hole states ( $E_C^{n=1}-E_{LH}^{n=1}$ ) **3815**. Curve **3820** shows the total spectrum that is observable. The smaller energy width of the emission peaks compared to FIG. **37** is due to the smaller coupling between nearest neighbour GaN potential minima and thus the formation of narrower energy width minibands in both the conduction and respective valence bands.

FIG. **39** shows a graph **3900** of the emission spectrum of a 3:6 superlattice for the lowest energy transition of the n=1 conduction states and the n=1 heavy hole states ( $E_C^{n=1}-E_{HH}^{n=1}$ ) **3905**, the lowest energy transition of the n=1 conduction states and the n=1 crystal field split states ( $E_C^{n=1}-E_{CH}^{n=1}$ ) **3910**, and the lowest energy transition of the n=1 conduction states and the n=1 light hole states ( $E_C^{n=1}-E_{LH}^{n=1}$ ) **3915**. Curve **3920** shows the total spectrum that is observable.

FIG. **40** shows a graph **4000** of the emission spectrum of a 4:8 superlattice for the lowest energy transition of the n=1 conduction states and the n=1 heavy hole states ( $E_C^{n=1}-E_{HH}^{n=1}$ ) **4005**, the lowest energy transition of the n=1 conduction states and the n=1 crystal field split states ( $E_C^{n=1}-E_{CH}^{n=1}$ ) **4010**, and the lowest energy transition of the n=1 conduction states and the n=1 light hole states ( $E_C^{n=1}-E_{LH}^{n=1}$ ) **4015**. Curve **4020** shows the total spectrum that is observable.

FIG. **41** shows a graph **4100** of the emission spectrum of a 5:10 superlattice for the lowest energy transition of the n=1 conduction states and the n=1 heavy hole states ( $E_C^{n=1}-E_{HH}^{n=1}$ ) **4105**, the lowest energy transition of the n=1 conduction states and the n=1 crystal field split states ( $E_C^{n=1}-E_{CH}^{n=1}$ ) **4110**, and the lowest energy transition of the n=1 conduction states and the n=1 light hole states ( $E_C^{n=1}-E_{LH}^{n=1}$ ) **4115**. Curve **4120** shows the total spectrum that is observable.

Of particular importance is the achievement of ( $E_C^{n=1}-E_{HH}^{n=1}$ ) optical transitions that are always the lowest energy emission and thus enable efficient vertically emissive devices of the form shown in FIG. **7**.

FIG. **42** shows a graph **4200** of the optical emission spectra for the heavy hole transition for each M:N pair plotted in FIGS. **37** to **41**. In general larger GaN layer thicknesses result in quantized energy levels that are closer to the GaN band edges and thus result in longer emission wavelengths. Conversely, thinner GaN layers improve the overlap of the lowest energy quantized conduction and valence band states and thus improve the oscillator strength and emission intensity. It is found that for GaN epilayers in excess of 8 to 10 monolayers the overlap integral is severely degraded and poor optical emission results. For application to ultraviolet and deep ultraviolet devices, the M:N configurations of FIG. **42** are found to be optimal and or desired. Shorter emission wavelengths are possible using superlattice unit cells comprising AlN and  $Al_xGa_{1-x}N$  compositions. To preserve the TE character of the emission it is found that  $Al_xGa_{1-x}N$  where x is less than or equal to about 0.5 is preferred.

The above can be used to design semiconductor structures, such as the semiconductor structure of FIGS. **1** to **8**. For example, the M:N configuration of the unit cells of the

i-type active region, the n-type active region and the p-type active region can be selected to produce an emission wavelength from the i-type active region that is longer than the absorption edge of the n-type active region and the p-type active region. Further, embodiments of the invention can be designed with a constant average alloy fraction throughout the semiconductor structure which further improves the crystal quality of the resulting structure.

FIGS. 43 and 44 show graphs of the calculated optical emission wavelength of the lowest energy transition between the allowed superlattice conduction band states and the heavy hole states for unit cells comprising exclusively AlN and GaN epilayers. FIG. 43 discloses the emission wavelength for N=2M superlattices having  $x_{ave}^{SL=2/3}=0.667$ , whereas FIG. 44 discloses the emission wavelength for N=M superlattice and  $x_{ave}^{SL=1/2}=0.50$ . The curves 4300 and 4400 show the variation in the lowest energy optical emission wavelength as a function of the unit cell period  $\Lambda_{SL}$  which has a corresponding M:N configuration. From the graphs it can be seen that the optical emission can be tuned over a wide and desirable optical range spanning from about 230 nm to less than 300 nm.

In one example, a semiconductor structure is formed of distinct superlattice regions. The unit cells of each superlattice have an Al fraction  $x_{ave}^{SL=2/3}$  and are formed exclusively of a GaN and an AlN layer. The desired design wavelength for a light emitting device comprising the semiconductor structure is, for example,  $\lambda_e=265$  nm. Thus, referring to FIG. 43, an M:N=3:6 unit cell is selected of the i-type active region. The device comprises an n-type active region formed atop a transparent substrate using a superlattice unit cell that is substantially transparent to the desired design wavelength  $\lambda_e$ . Similarly, the device comprises a p-type active region that is substantially transparent to the desired design wavelength  $\lambda$ . The superlattice in the n-type active region can therefore be selected to have M:N=1:2 unit cells and the superlattice in the p-type active region can be selected to have M:N=2:4 unit cells. This will improve the activated heavy hole concentration and provide an improved hole wavefunction injection into a portion of the M:N=3:6 unit cells of the superlattice in the i-type active region.

The i-type active region can be partitioned into two distinct superlattices, being a first superlattice with M:N=2:4 unit cells and a second superlattice with M:N=3:6 unit cells. The first superlattice is positioned between the n-type active region and the second superlattice. The second superlattice is positioned between the first superlattice and the p-type active region. The first superlattice acts as an electron energy filter for injecting preferred electrons into the electron-hole recombination region (EHR) defined by the second superlattice. This configuration therefore provides improved carrier transport of electrons and holes throughout the semiconductor structure. The EHR of the second superlattice is positioned close to the hole reservoir due to the inherently low hole mobility in the group III metal nitrides. Therefore, a light emitting device can be produced having a semiconductor structure having [n-type 1:2/i-type 2:4/i-type 3:6/p-type 2:4] superlattice regions. The total thickness of the i-type active region can also be optimized.

FIGS. 45 and 46 show graphs of a conduction band edge 4510 and 4610 and a heavy hole valence band edge 4505 and 4605 in electron volts (eV) along the growth direction z for semiconductor structures comprising 100 periods of n-type M:N=1:2 unit cells in the n-type active region and 100 periods of p-type M:N=1:2 unit cells in the p-type active region. The unit cells are exclusively constructed from c-plane oriented GaN and AlN monolayered films with a

constant Al fraction of  $x_{ave}^{SL=2/3}$ . The i-type active region similarly has a constant Al fraction of  $x_{ave}^{SL=2/3}$  but has a large period in order to tune the emission wavelength to a longer wavelength. FIG. 45 shows a graph for a semiconductor structure that has 25 periods of 2:4 unit cells in the i-type active region 4530, whereas FIG. 46 shows a graph for a semiconductor structure that has 100 periods of 2:4 unit cells in the i-type active region 4630. The built-in depletion region electric field  $E_d(z)$  4520, due to the p-type and n-type active regions, in FIG. 45 is larger than the built-in depletion region electric field  $E_d(z)$  4620 in FIG. 46. The built-in depletion region electric field  $E_d(z)$  is affected by the total thickness of the i-type active region superlattice and places yet another Stark shifting potential across the superlattice confined states. It is found that this quantum confined superlattice Stark effect (QC-SL-SE) can be used to further tune the optical properties of the device.

FIG. 47 shows the graphs of FIGS. 45 and 46 on a single graph for comparison. An optional p-GaN contact layer that is inserted above the p-type active region pins the Fermi level via an induced two-dimensional hole gas (2DHG). The devices have a metal polar growth orientation along the growth direction z.

FIG. 48 shows a graph of the calculated lowest energy quantized electron wavefunctions 4800 within the i-type active region of the semiconductor structure referred to in FIG. 45 under the influence of the built-in depletion electric field. Compared to the semiconductor structure with no depletion electric field, the wavefunctions are observed to be blue shifted and there is a reduction of the resonant tunneling between nearest neighbours. The conduction band edge 4510 is plotted as a reference.

FIG. 49 shows a graph of the calculated quantized lowest energy heavy hole wavefunctions 4900 within the i-type active region of the semiconductor structure referred to in FIG. 46 under the influence of the built-in depletion electric field. The heavy hole band edge 4605 is plotted as a reference.

FIGS. 50A and 50B show graphs of the emission spectra from the i-type active regions of the devices referred to in FIGS. 45 and 46, respectively. FIG. 50A shows the emission spectra for the optical transitions between the lowest energy n=1 conduction band states and their respective HH 5005, LH 5010 and CH 5015 valence bands and the total TE emission spectrum 5020 in the device of FIG. 45. FIG. 50B shows the emission spectra for the optical transitions between the lowest energy n=1 conduction band states and their respective HH 5025, LH 5035 and CH 5030 valence bands and the total TE emission spectrum 5040 in the device of FIG. 46.

The device of FIG. 45 has a larger built-in electric field than the device of FIG. 46 due to the thinner i-type active region. This larger built-in electric field breaks the coupling between adjacent unit cells in the i-type active region, produces a small blue shift in the emission energy and reduces the emission spectral line width. Comparing FIG. 50A to FIG. 50B, it can be seen that there is a reduction in the full width at half maximum (FWHM) of the low energy side of the peak emission and a blue shift of the low energy emission edge due to the larger built-in electric field. FIG. 50B shows a larger integrated luminescence than FIG. 50A due to the large number of periods in i-type active region of the device of FIG. 46.

FIG. 51 schematically describes the influence of the built-in depletion field 5130 having potential energy 5135 along a distance 5140 that is parallel to a growth direction 5110. The superlattice band diagram without a built-in

depletion field is shown as the spatial conduction band edge **5115** and the vertical axis **5105** represents energy. The delocalized electron wavefunction **5120** is coupled between adjacent GaN regions by virtue of quantum mechanical tunnelling through the high potential energy AlN barriers. The internal pyroelectric and piezoelectric fields are also shown and representative of a metal polar oriented growth. The tunnelling of the wavefunctions **5120** results in an energy miniband **5125** for the allowed quantized conduction states. Application of a linearly increasing potential **5130** such as occurs with the built-in depletion field, results in spatial band structure **5160**. The resulting wavefunctions of the superlattice with application of the depletion field **5130** generates the wavefunctions **5145** and **5155** which are no longer resonantly coupled to their nearest neighbour GaN potential minima. The quantized allowed energy states of the band structure **5160** now has discrete energy states **5165** and **5170** that are higher in energy compared to the miniband energy states **5125**.

This effect can be modified by application of a depletion electric field across a nitrogen-polar oriented growth, with a resulting lowering of the energy of Stark split states. This is particularly useful for example, for a nitrogen polar p-i-n superlattice device composed of only one unit cell type, such as an M:N=3:6 unit cell having a GaN layer and an AlN layer. The built-in depletion field across the superlattice having M:N=3:6 unit cells cause an emission energy to be stark shifted to longer wavelengths (i.e., red-shifted) and will not be substantially absorbed in surrounding p-type and n-type active regions having M:N=3:6 unit cells.

In general, a metal polar oriented growth produces blue shift in the emission spectrum of the i-type active region or i-type active region of a n-i-p device due to a p-up epilayer stack. That is, for a depletion electric field as shown for a device formed in the order: substrate, n-type active region, i-type active region, p-type active region [SUB/n-i-p]. Conversely, a redshift is observed in the emission spectrum of the i-type active region for a p-i-n device formed as a p-down epilayer stack, that is, [SUB/p-i-n].

Conversely, a nitrogen polar oriented growth produces a blue shift in the emission spectrum of the i-type active region of a n-i-p device due to the depletion electric field, and a redshift in the emission spectrum of the i-type active region of a p-i-n device due to the depletion electric field.

The present invention provides many benefits over the prior art, including improved light emission, especially at UV and Deep UV (DUV) wavelengths. For example, the use of ultrathin layered superlattices enables photons to be emitted vertically, i.e. perpendicular to the layers of the device, as well as horizontally, i.e. parallel with the layers. Furthermore, the present invention provides spatial overlap between the electron and hole wavefunctions enabling improved recombination of electrons and holes.

In particular, for the application of ultra-violet devices, GaN proves extremely beneficial for the narrower band gap material and AlN for the wider bandgap material. GaN is inherently a vertically emissive material when deposited on c-plane surfaces, whereas AlN emits substantially with TM optical polarizations, i.e. in the plane of the sub-layers.

The thickness of the first layer and second layer of the unit cells can be used to select the quantisation energy of electrons and holes and the coupling of electrons in the conduction band. For example, the thickness of layers of GaN can be used to select the quantization energy of electrons and holes and the thickness of layers of AlN can control the coupling of electrons in conduction band. The ratio of thickness of the layers of GaN to the layers of AlN can be used to select the average in-plane lattice constant of the superlattice. Hence, the optical transition energy of a

given superlattice can be altered by choice of both the average unit cell composition and the thickness of the each layer of each unit cell.

Further advantages of the present invention include: simpler manufacturing and deposition processes; customisable electronic and optical properties (such as the wavelength of the emitted light) suitable for high efficiency light emission; optimised optical emission polarisation for vertically emissive devices when deposited on c-plane oriented surfaces; improved impurity dopant activation for n-type and p-type conductivity regions; and strain managed monolayers enabling optically thick superlattices to be formed without excessive strain accumulation. For example, aperiodic superlattices can be used to prevent strain propagation and enhance optical extraction.

Furthermore, spreading out the electron and or hole carrier spatial wavefunctions within the electron-hole recombination regions improves both the carrier capture probability by virtue of increase volume of material, and also improves the electron and hole spatial wavefunction overlap and thus improves the recombination efficiency of the device over prior art.

In this specification, the term "superlattice" refers to a layered structure comprising a plurality of repeating unit cells including two or more layers, where the thickness of the layers in the unit cells is small enough that there is significant wavefunction penetration between corresponding layers of adjacent unit cells such that quantum tunnelling of electrons and/or holes can readily occur.

In this patent specification, adjectives such as first and second, left and right, front and back, top and bottom, etc., are used solely to define one element from another element without necessarily requiring a specific relative position or sequence that is described by the adjectives. Words such as "comprises" or "includes" are not used to define an exclusive set of elements or method steps. Rather, such words merely define a minimum set of elements or method steps included in a particular embodiment of the present invention. It will be appreciated that the invention may be implemented in a variety of ways, and that this description is given by way of example only.

The above description of various embodiments of the present invention is provided for purposes of description to one of ordinary skill in the related art. It is not intended to be exhaustive or to limit the invention to a single disclosed embodiment. As mentioned above, numerous alternatives and variations to the present invention will be apparent to those skilled in the art of the above teaching. Accordingly, while some alternative embodiments have been discussed specifically, other embodiments will be apparent or relatively easily developed by those of ordinary skill in the art. Accordingly, this patent specification is intended to embrace all alternatives, modifications and variations of the present invention that have been discussed herein, and other embodiments that fall within the spirit and scope of the above described invention.

The reference to any prior art in this specification is not, and should not be taken as, an acknowledgement or any form of suggestion that the prior art forms part of the common general knowledge in Australia or elsewhere.

The invention claimed is:

**1.** An optoelectronic device comprising a semiconductor structure including:

- a p-type active region comprising a p-type superlattice;
- an n-type active region comprising an n-type superlattice;
- and
- an i-type active region between the n-type active region and the p-type active region comprising an i-type superlattice;

wherein:

the semiconductor structure is comprised solely of one or more superlattices;  
 the p-type superlattice is comprised of a plurality of p-type unit cells;  
 the n-type superlattice is comprised of a plurality of n-type unit cells;  
 the i-type superlattice is comprised of a plurality of i-type unit cells;  
 an average alloy content of the plurality of p-type, n-type and i-type unit cells is constant along a growth direction;  
 the p-type unit cells comprise a first set of at least two distinct substantially single crystal layers;  
 the n-type unit cells comprise a second set of at least two distinct substantially single crystal layers;  
 the i-type unit cells comprise a third set of at least two distinct substantially single crystal layers;  
 a combined thickness of the third set of at least two distinct substantially single crystal layers is thicker than a combined thickness of the first set of at least two distinct substantially single crystal layers;  
 the combined thickness of the third set of at least two distinct substantially single crystal layers is thicker than a combined thickness of the second set of at least two distinct substantially single crystal layers; and  
 all distinct substantially single crystal layers comprised in the first, second and third sets of at least two distinct substantially single crystal layers have thicknesses that are less than or equal to a critical layer thickness required to maintain elastic strain.

2. The optoelectronic device of claim 1 wherein the i-type active region has a thickness of greater than or equal to 1 nm and less than or equal to 100 nm.

3. The optoelectronic device of claim 1 wherein the semiconductor structure is constructed by epitaxial layer growth along the growth direction.

4. The optoelectronic device of claim 3 wherein the first, second and third sets of at least two layers each have a thickness of less than or equal to 6 monolayers of a material of which the respective layer is composed along the growth direction.

5. The optoelectronic device of claim 3 wherein one of the distinct substantially single crystal layers within at least a portion of the first, second or third sets of at least two distinct substantially single crystal layers comprises 1 to 10 monolayers of atoms along the growth direction and the other one or more layers in each of the respective unit cells comprise a total of 1 to 10 monolayers of atoms along the growth direction.

6. The optoelectronic device of claim 3 wherein the at least two distinct substantially single crystal layers of each of the first, second or third sets of at least two distinct substantially single crystal layers have a wurtzite crystal symmetry and have a crystal polarity in the growth direction that is either a metal-polar polarity or nitrogen-polar polarity.

7. The optoelectronic device of claim 6 wherein the crystal polarity is spatially varied along the growth direction, the crystal polarity being alternately flipped between the nitrogen-polar polarity and the metal-polar polarity.

8. The optoelectronic device of claim 3 wherein the optoelectronic device is configured as a light emitting device and light is generated by recombination of electrically active holes and electrons supplied by the p-type active region and the n-type active region, the recombination occurring in the i-type active region.

9. The optoelectronic device of claim 8 wherein light emitted by the optoelectronic device is ultra violet light in the wavelength range of 150 nm to 280 nm.

10. The optoelectronic device of claim 8 wherein:  
 the optoelectronic device emits light having a substantially transverse electric optical polarization with respect to the growth direction; and  
 the optoelectronic device operates as a vertically emitting cavity device with light spatially generated and confined along a direction substantially perpendicular to the plane of the one or more layers of the unit cells of the one or more superlattices of the semiconductor structure.

11. The optoelectronic device of claim 10 wherein:  
 the vertically emitting cavity device has a vertical cavity disposed substantially along the growth direction and formed using metallic reflectors spatially disposed along one or more portions of the semiconductor structure;  
 the reflectors are made from a high optical reflectance metal;  
 the vertical cavity is defined by an optical length between the reflectors being less than or equal to a wavelength of the light emitted by the device; and  
 the wavelength is determined by optical emission energy of the one or more superlattices comprising the semiconductor structure and optical cavity modes determined by the vertical cavity.

12. The optoelectronic device of claim 11 wherein the high optical reflectance metal is aluminium (Al).

13. The optoelectronic device of claim 8 wherein:  
 a reflector layer is provided to improve out coupling of the light generated within the semiconductor structure; and  
 the reflector layer is positioned atop the optoelectronic device to substantially retroreflect emitted light from an interior of the device.

14. The optoelectronic device of claim 1, further comprising a crystalline substrate on which the semiconductor structure is grown wherein a buffer layer is grown first on the substrate followed by the semiconductor structure with the buffer layer acting as a strain control mechanism providing an in-plane lattice constant.

15. The optoelectronic device of claim 14 wherein the buffer layer includes one or more buffer layer superlattices.

16. The optoelectronic device of claim 1 wherein each of the first, second and third sets of at least two distinct substantially single crystal layers comprises at least one of the following compositions:

a binary composition single crystal semiconductor material ( $A_xN_y$ ), where  $0 < x \leq 1$  and  $0 < y \leq 1$ ;

a ternary composition single crystal semiconductor material ( $A_uB_{1-u}N_y$ ), where  $0 \leq u \leq 1$  and  $0 < y \leq 1$ ;

a quaternary composition single crystal semiconductor material ( $A_pB_qC_{1-p-q}N_y$ ), where  $0 \leq p \leq 1$ ,  $0 \leq q \leq 1$  and  $0 < y \leq 1$ ;

where A, B and C are distinct metal atoms selected from group II and/or group III elements and N are cations selected from at least one of a nitrogen, oxygen, arsenic, phosphorus, antimony, and fluorine.

17. The optoelectronic device of claim 1 wherein each of the first, second and third sets of at least two distinct substantially single crystal layers comprises at least one of the following compositions:

a group III metal nitride material ( $M_xN_y$ );

a group III metal arsenide material ( $M_xAs_y$ );

a group III metal phosphide material ( $M_xP_y$ );

a group III metal antimonide material ( $M_xSb_y$ );

## 41

a group II metal oxide material ( $M_xO_y$ );  
 a group II metal fluoride material ( $M_xF_y$ );  
 where  $0 < x \leq 3$  and  $0 < y \leq 4$ , and where M is a metal.

18. The optoelectronic device of claim 1 wherein each of the first, second and third sets of at least two distinct substantially single crystal layers comprises at least one of the following compositions:

aluminium nitride (AlN);  
 aluminium gallium nitride ( $Al_xGa_{1-x}N$ ) where  $0 \leq x < 1$ ;  
 aluminium indium nitride ( $Al_xIn_{1-x}N$ ) where  $0 \leq x < 1$ ;  
 aluminium gallium indium nitride ( $Al_xGa_yIn_{1-x-y}N$ ) where  $0 \leq x < 1$ ,  $0 \leq y \leq 1$  and  $0 < (x+y) < 1$ .

19. The optoelectronic device of claim 1 wherein one or more layers of one or more of the first, second or third sets of at least two distinct substantially single crystal layers is not intentionally doped with an impurity species.

20. The optoelectronic device of claim 1 wherein one or more layers of one or more of the first, second and third sets of at least two distinct substantially single crystal layers is intentionally doped with one or more impurity species or formed with one or more impurity species.

21. The optoelectronic device of claim 20 wherein the one or more impurity species in the n-type active region are selected from:

silicon (Si);  
 germanium (Ge);  
 silicon-germanium ( $Si_xGe_{1-x}$ ), where  $0 < x < 1$ ;  
 crystalline silicon-nitride ( $Si_xN_y$ ), where  $0 < x < 3$  and  $0 < y < 4$ ;  
 crystalline germanium-nitride ( $Ge_xN_y$ ), where  $0 < x < 3$  and  $0 < y < 4$ ;  
 crystalline silicon-aluminium-gallium-nitride ( $Si_u[Al_xGa_{1-y}]_zN_v$ ) where  $u > 0$ ,  $x > 0$ ,  $0 < y < 1$ ,  $z > 0$  and  $v > 0$ ;  
 or  
 crystalline germanium-aluminium-gallium-nitride ( $Ge_u[Al_xGa_{1-y}]_zN_v$ ) where  $u > 0$ ,  $x > 0$ ,  $0 < y < 1$ ,  $z > 0$  and  $v > 0$ .

22. The optoelectronic device of claim 20 wherein the one or more impurity species in the p-type active region are selected from:

magnesium (Mg);  
 zinc (Zn);

## 42

magnesium-zinc ( $Mg_xZn_{1-x}$ ), where  $0 \leq x \leq 1$  crystalline magnesium-nitride ( $Mg_xN_y$ ), where  $0 < x \leq 3$  and  $0 < y \leq 2$ ; or magnesium-aluminium-gallium-nitride ( $Mg_u[Al_xGa_{1-y}]_zN_v$ ), where  $u > 0$ ,  $x > 0$ ,  $0 < y < 1$ ,  $z > 0$  and  $v > 0$ .

23. The optoelectronic device of claim 20 wherein the one or more impurity species in the n-type active region or the p-type active region are selected from:

hydrogen (H);  
 oxygen (O);  
 carbon (C); or  
 fluorine (F).

24. The optoelectronic device of claim 20 wherein the one or more impurity species are incorporated post growth via ion-implantation.

25. The optoelectronic device of claim 20 wherein at least a portion of at least one of the one or more of the p-type, n-type and i-type superlattices includes uniaxial strain or a biaxial strain to enhance the activation energy of an B intentionally doped region to improve an electron or hole carrier concentration.

26. The optoelectronic device of claim 1 wherein a first lateral contact extends partially into the n-type active region from a first contact layer formed on a surface of the n-type active region.

27. The optoelectronic device of claim 26 wherein a second lateral contact extends partially into the p-type active region from a second contact layer formed on a surface of the p-type active region.

28. The optoelectronic device of claim 27 wherein the second lateral contact is surrounded by a layer of p-type GaN between the second lateral contact and the p-type active region.

29. The optoelectronic device of claim 27 wherein the second contact layer is a metal contact layer and a p-type contact layer is formed between the p-type active region and the metal contact layer.

30. The optoelectronic device of claim 1 wherein the first, second and third sets of at least two distinct substantially single crystal layers each consist of two distinct substantially single crystal layers.
